While alloying elements may initially determine the protective nature of an oxide scale, the response of this oxide scale to stress is often crucial in determining the long-term oxidation performance of an alloy in an industrial environment.<sup>118</sup> The stresses in an oxide scale may arise both internally (because of growth stresses) and externally (because of applied stresses).<sup>119</sup> In general, oxide scales do not possess sufficient slip systems for plasticity and thus rely upon diffusion-controlled creep for plastic deformation and stress relief.<sup>120</sup> At temperatures below approximately 600 °C, only elastic deformation is possible and stress relief by cracking is likely to occur. If the scale-metal interface is strong, and the bulk oxide is weak, through-scale cracking results when the combined stresses exceed a critical value.<sup>121</sup> If the interface has a lower strength than the oxide bulk strength, decohesion occurs first. A minimum energy is required for cracking or decohesion.<sup>122,123</sup> Evans and Lobb<sup>121</sup> have calculated that cracking occurs when the strain energy per unit volume ( $w^*$ ) of oxide contained in layer thickness ( $z$ ) equals the work required for internal cracking ( $G_c$ ) or decohesion ( $G_d$ ). For internal cracking,

$$w^* = \frac{8PG_c}{fL} \sim \frac{4G_c}{fL} \quad [4]$$

where  $L$  is the side length of unit volume;  $f$ , the fraction of stored energy in the oxide;  $G_c$ , the energy for unit area of cracked oxide surface; and  $P$  is the geometric parameter ( $\sim 0.5$ ). For decohesion,

$$zw^* = \frac{G_d}{f} \quad [5]$$

where  $f$  is the energy/unit area of fresh metal at the oxide-metal interface.

Through-scale cracking may not necessarily be detrimental to an alloy if rapid scale healing can occur,<sup>124</sup> and scale delamination can reduce the total scaling rate if the scale remains adjacent to the alloy surface.<sup>119,125</sup> In this instance, scale separation confounds the transport of metal ions across the interface into the oxide. However, if through-scale cracking occurs in conjunction with delamination, scale spalling may follow,<sup>121</sup> with an attendant loss of

protection. For pure metals which oxidize in a parabolic manner, repetitive scale spalling may produce a much increased total metal loss over time, since the reaction kinetics continually revert to the initial rapid period of the oxidation curve and parabolic kinetics ensue.

The majority of heat-resisting alloys contain at least one element that is selectively oxidized (e.g., Cr, Si, Al). The resulting scale is highly protective, but depletion of the secondary element may occur if the diffusion rate of this element in the alloy is low. Then repetitious loss of the scale can be profoundly detrimental to long-term performance, since depletion of the alloying element near the surface may occur to such an extent that its concentration falls below the critical level for the exclusive reformation of the highly protective scale.<sup>126,127</sup>

#### 1.22.6.1 Growth Stresses

As indicated earlier, protective oxide scales typically have a PBR greater than unity and are, therefore, less dense than the metal from which they have formed. As a result, the formation of protective oxides invariably results in a local volume increase or a stress-free oxidation strain.<sup>128,129</sup> If lateral growth occurs, then compressive stresses can build up, and these are intensified at convex and reduced at concave interfaces by the radial displacement of the scale due to outward cation diffusion (Figure 7).<sup>48,129,130</sup>

The reduced oxidation near sample corners is related to these stress effects, either by retarded diffusion or by modified interfacial reactions.<sup>128</sup> Manning<sup>131</sup> described these stresses in terms of the conformational strain and distinguished between anion and cation diffusion, and concave and convex surfaces. He defined a radial vector  $M$ , describing the direction and extent of displacement of the oxide layer in order to remain in contact with the retreating metal surface, where

$$M = \frac{V_{ox}}{V_{me}} (1 - a) (1 - v) \quad [6]$$

and  $V_{ox}/V_{me}$  is the PBR,  $a$  is the amount of oxide formed at the surface, and  $v$  is the volume gain due to vacancy injection into the metal. If  $v$  is zero, the sign of  $M$  depends upon the predominance of anion ( $a = 0$ ) or cation ( $a = 1$ ) diffusion. The enforced radial displacement ( $\delta y$ ) of the oxide layer results in a tangential or radial reaction stress in both the oxide and the metal. The strain rate ( $\delta e/\delta t$ ) of the oxide layer

**Figure 7** Oxide growth stresses on curved surfaces. Reproduced from Hsueh, C. H.; Evans, A. G. *J. Appl. Phys.* **1983**, 54, 6672.

then depends upon the radius of curvature ( $R$ ) and the rate of metal loss ( $\delta b/\delta t$ ) as

$$\frac{\delta e}{\delta t} = \frac{M(\delta b)}{R(\delta t)} \quad [7]$$

This leads to high strains on regions of high curvature and zero strain on a flat surface. If new growth occurs stress free, then the oldest region of oxide will be the most highly stressed, this being located at the oxide surface for anion-controlled growth and at the oxide-metal interface for cation-controlled growth. Hsueh and Evans<sup>128</sup> carried out a similar analysis and calculated the distribution of radial and tangential stress within the oxide scale as a function of scale thickness and specimen geometry.

Whisker growth is a process often reported for the relief of compressive growth stresses during oxidation.<sup>132-134</sup> This whisker formation and scale buckling of thin hematite layers have been linked to the stresses arising from oxide formation at the magnetite-hematite interface as a result of the counter-current of cation and anion diffusion in both oxides.<sup>130</sup> Acoustic emission studies of 2.25% Cr-1% Mo steel at 900 °C have shown that, as the oxide thickness increases, growth stress builds up in the scale and is relieved by scale cracking.<sup>135</sup>

#### 1.22.6.2 System-Applied Stresses

The tensile failure strain of oxides grown on EN2 steel between 600 and 900 °C lies in the range  $1 \times 10^{-4}$  to

$2.5 \times 10^{-4}$ .<sup>(136)</sup> Components in service may be stressed beyond these failure strains, leading to scale cracking.

Ward *et al.*<sup>137</sup> have shown that, under cyclical loading, the oxidation rate of steels is similar to that under unstressed isothermal conditions, provided the fatigue stress is below the stress required to exceed the scale failure strain. If, however, the failure strain is exceeded, the oxidation rate is accelerated because of repetitive scale failure, and linear kinetics are observed.

Low-cycle fatigue loading of 9.5% Cr steel at 650 °C in air has been shown to enhance uniform scale formation as well as promote nodular scale formation at cracks.<sup>124</sup> However, no cracks were found in the scale after exposure, indicating that any cracks that form must heal very quickly. This healing of cracks was attributed to the overgrowth of the chromium-rich oxide by an iron-rich oxide.

#### 1.22.6.3 Thermal Stresses

Under thermal cycling conditions, the principal source of stress within the oxide scale is the temperature change.<sup>121</sup> Christl *et al.*<sup>125</sup> have noted that, when cooling 2.25% Cr-1% Mo steel from 600 °C in air, compressive stresses build up in the hematite, while tensile stresses build up in the magnetite and spinel layers. This arises because the thermal expansion coefficients of the individual oxide layers increase in the order  $\alpha_{\text{metal}} < \alpha_{\text{spinel}} < \alpha_{\text{magnetite}} < \alpha_{\text{hematite}}$ .<sup>119</sup>

Multilaminated scales have been reported following thermal cycling,<sup>138</sup> and Rolls and Nematollahi<sup>139</sup>

have studied the influence of thermal cycling on the oxidation of 1% Cr–0.5% Mo low-carbon steel. The oxidation kinetics were found to be mostly parabolic, with thin scales (10  $\mu\text{m}$ ) more prone to spalling than thick scales (20  $\mu\text{m}$ ). The authors reported that the higher the temperature drop on cycling, the greater the degree of scale disruption. They derived a qualitative relationship to describe this behavior:

$$Y = \frac{f(NO)}{x} \quad [8]$$

where  $Y$  is the degree of scale detachment,  $N$  is the number of cycles,  $x$  is the thickness, and  $O$  is the cooling rate. This implies that thicker scales cooled slowly show less detachment than thinner scales cooled rapidly. The oxide scale comprised spinel, magnetite, and wüstite, with only the spinel layer remaining adherent during thermal cycling. From this, the authors concluded that the bulk scale cohesive strength was less than the inner spinel adhesive strength. Scale detachment was observed at voids and microcracks produced at the outer–spinel interface during isothermal oxidation. Hence, the number of scale layers that became detached during thermal cycling was governed by the number of parallel rows of voids in the scale and not by the number of thermal cycles.

### 1.22.7 Commercial Low-Alloy Steels in Air or Oxygen

Simms and Little<sup>140</sup> have examined the early stages of scale growth on 2.25% Cr–1% Mo steel at 600 °C in dry flowing oxygen. Between 1 and 22 h, they found that a thick oxide layer spreads laterally over a thin oxide layer. After 50 h, no thin areas of oxide layer were left. Whiskers gradually developed on the outer surface and these were well defined after 100 h. Fracture sections of the oxide revealed that the thin scales were duplex, whereas the thicker scale was triplex, with a middle layer of  $\text{Fe}_3\text{O}_4$  which spread laterally with time. The authors concluded that the first phases to develop were fine equiaxed  $\alpha\text{-Fe}_2\text{O}_3$  overlying a doped spinel. Later, nucleation and lateral spread of coarse columnar grains of  $\text{Fe}_3\text{O}_4$  occurred between the two first-formed layers. The  $\text{Fe}_2\text{O}_3$  appears to reach a limiting thickness at which time  $\text{Fe}_3\text{O}_4$  nucleates.

One of the authors<sup>141</sup> has carried out exposures of a range of low-alloy steels (up to 5% Cr) in laboratory air between 500 and 850 °C. Plain carbon steel displayed a duplex scale, comprising 75%  $\text{Fe}_3\text{O}_4$  and

25%  $\text{Fe}_2\text{O}_3$  at all temperatures below 600 °C (Figure 8). Above 600 °C, a coarse, columnar-grained layer of FeO occupying approximately 90% of the scale thickness was observed. For the Cr-containing steels, a distinct spinel phase was observed at temperatures in excess of around 615 °C, with all of the Cr, Mo, and V incorporated within this layer, beneath the  $\text{Fe}_3\text{O}_4$  and  $\text{Fe}_2\text{O}_3$ . FeO was not observed in the scale until temperatures exceeded 650 °C, the FeO appearing as a fourth layer between the spinel and  $\text{Fe}_3\text{O}_4$  layers. Parabolic oxidation kinetics were observed for all steels at all temperatures. Below 600 °C, there was little difference in the oxidation kinetics between the chromium steels until the Cr level reached around 5%, this difference mainly arising because of an increasing activation energy for  $\text{Fe}_3\text{O}_4$  growth with increasing Cr content. There was no significant difference in the activation energy for  $\text{Fe}_2\text{O}_3$  growth, irrespective of the Cr content of the steel (Figure 9).

## 1.22.8 Industrial Environments

### 1.22.8.1 Steam

Many low alloy steels are utilized as pressure vessels in high temperature applications in a number of

**Figure 8** Relative thickness of wüstite, magnetite and hematite on mild steel as a function of formation temperature.

**Figure 9** Arrhenius plot for the hematite thickening rate on mild steel and low-chromium alloy steels in air.

diverse and often aggressive environments. Metal wastage by oxidation and corrosion reduces the load bearing cross sectional area of a vessel wall and can have grave consequences in terms of creep rupture life, especially of thin walled components. Different environment parameters including temperature, gas/fluid composition, pressure, flow rates and alloy composition will define the oxidation mechanisms and rate of material wastage. It is therefore imperative that a material gains protection from the formation of a stable slow growing oxide scale. Wright and Pint<sup>142</sup> predict that in steam environments the protective behavior associated with the formation of a complete  $\text{Cr}_2\text{O}_3$  layer is not necessarily observed in FeCr alloys with Cr contents below 20%.

Jonsson *et al.*<sup>143</sup> compared the oxidation of iron at 600 °C in dry  $\text{O}_2$  and wet  $\text{O}_2$  (40%  $\text{H}_2\text{O}$ ) where a three layer scale is formed consisting of a haematite outer layer, a magnetite middle layer and a wüstite inner layer forming the metal–scale interface. All three layers grow with time, but with different growth rates, the overall rate being roughly parabolic in both environments. While the detrimental effects of water vapour on oxidation rates are well reported, there is no consensus regarding the causes of this effect, however, recent investigations into the effect of hydrogen-accelerated oxidation on scale growth and morphology has

offered a possible insight into the increased steam side oxidation of low alloy steels.<sup>144–146</sup>

In recent years the group of modified 9%Cr steels has been developed for utilization in high temperature environments including power generation. Although the mechanical properties of these steels have been optimized, it is now appreciated that steam side oxidation of these alloys may be the factor that limits their maximum service temperature. Oxide growth rates have been shown to increase exponentially with temperature<sup>142</sup> up to 700 °C, where the isothermal oxidation rates are observed to be parabolic. However, investigations (COST-522, Europe's Thermie and the U.S. Vision 21 programs) aimed at improving thermodynamic efficiency by increasing service temperatures suggested that linear kinetics prevailed at temperatures above 700 °C for steels with Cr contents in the range 1–15 wt%.<sup>142,147</sup>

9% Cr ferritic martensitic steels show acceptable oxidation resistance in dry air at high temperatures due to the formation of a protective scale; between 400 °C and 600 °C the scale comprises of  $\text{FeO}$ ,  $\text{Fe}_2\text{O}_3$ , and  $\text{Cr}_2\text{O}_3$ . However, operation atmospheres composed of water vapour or steam + oxygen are much more corrosive than dry air. Subsequent scales that grow are less protective than  $\text{Fe}_2\text{O}_3$ , or  $\text{Cr}_2\text{O}_3$ . Sanchez *et al.*<sup>148</sup> predicts the formation of  $\text{Fe}_3\text{O}_4$ ,  $\text{Fe}_2\text{O}_3$  and  $(\text{FeCr})_3\text{O}_4$  scales in 100%  $\text{H}_2\text{O}$  atmosphere at 650 °C on 9%Cr steels, in contrast, at 800 °C the scale is mainly composed of  $\text{Fe}_3\text{O}_4$  and  $(\text{FeCr})_3\text{O}_4$ .

Itagaki *et al.*<sup>149</sup> found that an addition of 3%Pd to steel NF616 (similar to modified 9Cr–1Mo) gave significant improvements in oxidation resistance in steam at 650 °C as the growth of a Cr rich  $(\text{Fe}_2\text{Cr})_2\text{O}_3$  rhombohedral structured oxide was observed in the absence of a magnetite layer. Czyska-Filemonowicz *et al.*<sup>150</sup> state that oxidation (weight gain) of P91 steel can increase 30 fold in atmospheres containing water vapour compared to dry air.

Tuurna *et al.*<sup>151</sup> also studied the effects of water vapour on the high temperature oxidation of low alloy steels. Tests on 2.25Cr–1Mo steels at constant temperature (550 °C) with variable moisture content (5%–10%–15%) revealed an increasing linear relationship between moisture content and mass gain after 360 hours. Further tests at fixed moisture (15%) and variable temperature result in a steep increase in oxidation occurring at higher temperatures as the oxide scale becomes nonprotective; the use of 2.25Cr–1Mo steels is thus restricted to temperatures below 580 °C.

Nakai *et al.*<sup>152</sup> report the effects of preoxidation of Fe, 10%Cr, 0.08%C ternary alloy on subsequent steam

oxidation.<sup>143</sup>  $\text{Cr}_2\text{O}_3$  scales containing a small amount of  $\text{Fe}_2\text{O}_3$  are formed during preoxidation offering short term improvements in oxidation resistance. After long-term oxidation in steam nodular like oxides are formed on the preoxidised specimen showing a clear resemblance both chemically and structurally to the oxides formed on non-preoxidised specimens.

It is understood that hydrogen dissolves inward when steam oxidation takes place on the surface of steels.<sup>145,146,152</sup> Thus it appears that hydrogen plays an important role in the accelerated growth of the oxide scale when the steels are exposed to a wet gas atmosphere. Nakai *et al.*<sup>152</sup> proposes a model, where hydrogen dissolves as a proton ( $\text{H}^+$  ion) in  $(\text{Fe}, \text{Cr})_3\text{O}_4$  modifying the point defect structure inducing significant changes in the ionic diffusivity in the oxide. For example, the dissolved hydrogen will decrease the diffusion rate of Cr ions in  $(\text{Fe}, \text{Cr})_3\text{O}_4$ . The ensuing inhibited ionic Cr supply to the oxide layer results in the attendant decrease of the Cr concentration in  $(\text{Fe}, \text{Cr})_3\text{O}_4$ . Subsequently an apparent increase in the diffusion rate of Fe ions in the oxide is observed. As the oxidation rate of Fe–Cr steels is determined mainly by the Fe diffusivity in the  $(\text{Fe}, \text{Cr})_3\text{O}_4$  layer,<sup>153</sup> hydrogen dissolution induces the accelerated growth of the oxide scale on the steels.

Low alloy steels containing a maximum Cr content of 9 wt% but excluding T/P91 display similar scale morphologies and tendency/mechanisms to spallation showing a laminated oxide scale. The initial formation of a magnetite outer layer and an inner spinel layer is followed by the formation of similar underlying duplex layers (Figure 10), possibly as a result of delamination of the original scale at the oxide–substrate interface.<sup>90</sup> Repetition of this process develops a multilayered scale consisting of repeated duplex magnetite and spinel layers, successive duplex layers becoming noticeably thinner. Exfoliation of

these scales has a propensity to occur along a plane between one of the sets of duplex layers or at the scale–metal interface and is likely to be a mechanism of stress relief. There is evidence that there are conditions where the scales formed on ferritic steels in steam can remain perfectly adherent for long times; for instance, from tests in a side loop on an operating boiler, Griess and Maxwell<sup>154</sup> reported that alloy T22 formed adherent scales throughout exposures for 28kh in 105 bar steam at 482 °C; at 538 °C exfoliation initiated after approximately 12kh. Alloys 9Cr–1Mo (0.46Si), 9Cr–2Mo, and Sandvik HT9 (11.4Cr) followed essentially the same kinetic behavior (and rates) as T22, but exhibited no signs of exfoliation at 482 and 538 °C after exposures of 28kh, 19kh, and 28kh, respectively.

The laminated scales of low alloy steels are rarely observed on T/P91 steel, instead a largely duplex scale is observed with an incomplete outer layer of haematite. The duplex layer consists of an outer magnetite layer underlayered with a spinel layer rich in Cr, Si and Mo in comparison to the alloy composition.

12%Cr alloy steels display duplex oxide scale similar to those initially formed on the lower alloy ferritic steels. The outer scale is predominantly magnetite and the inner layer is a Cr rich spinel. The inner layer shows morphology similar to that often observed in P91 scales of incomplete Cr rich bands.

As quoted in the EPRI report on oxidation of alloys in steam<sup>90</sup> “There are five possible scenarios by which the scale morphologies observed on ferritic steels in steam might develop. Thus, it is suggested that the development of the (initial) double-layered scales on ferritic steels in steam (under isothermal conditions before the onset of any transition to multi-layered scales) involves the following steps; note that, in order to reflect the uncertainty in the dominant transport modes in these scales, five possible pathways for oxide growth are suggested (Figure 11)”:

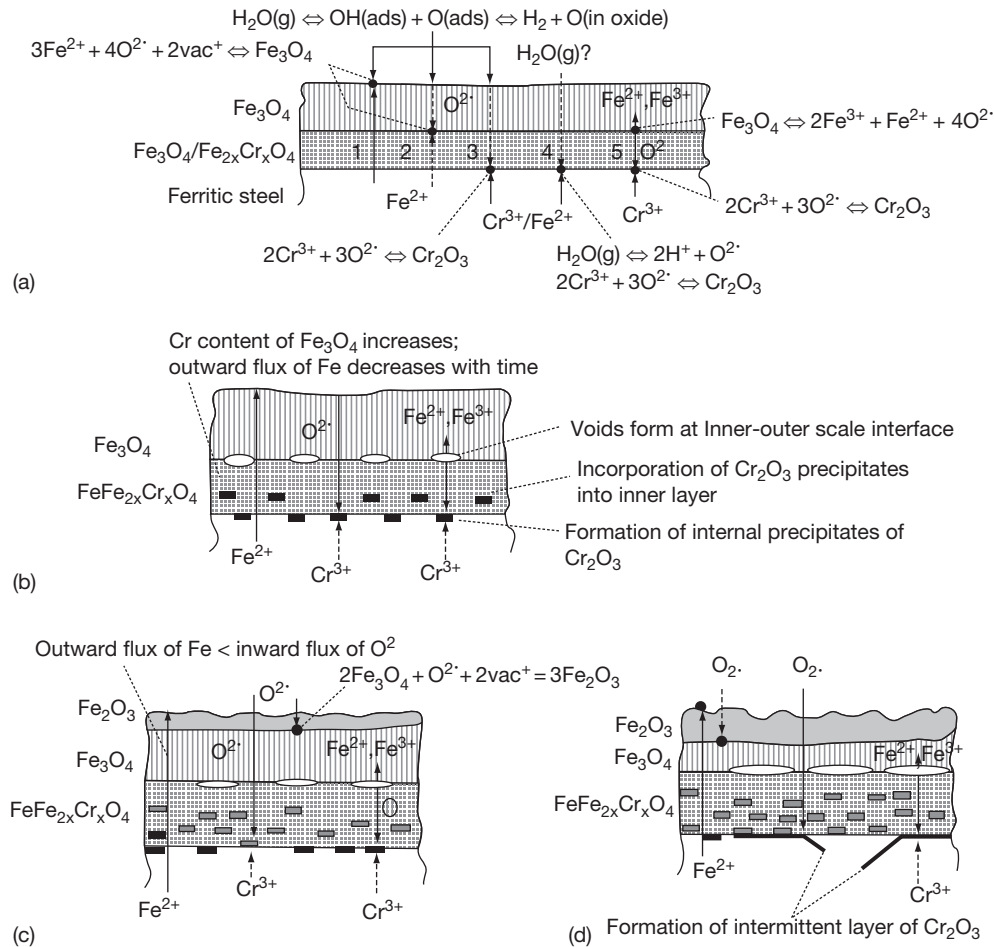

(a)

(b)

**Figure 10** (a) A cross section from a 2.25Cr–1Mo steel tube oxidised in steam. (b) A schematic representation defining the duplex layered system.<sup>155</sup>

**Figure 11** Schematic representation of the oxidation mechanisms observed in low alloy steels containing chromium.<sup>158</sup>

Path 1: outward diffusion of iron ions, which react at the oxide-steam interface with oxygen from the dissociation of steam to form fresh magnetite.<sup>156,157</sup>

Path 2: dissociation of steam at the oxide-steam interface, and diffusion of oxygen ions inwards via defects in the oxygen lattice, or “hydrogen defects”<sup>159</sup>; these react with iron ions diffusing from the alloy to form new oxide at the interface between the inner and outer oxide layers.

Path 3: dissociation of steam at the oxide-steam interface, and diffusion of oxygen ions inwards to the alloy-oxide interface, where they react with chromium in the alloy to form discrete internal particles of chromia.

Path 4: suggests that molecular steam is transported through the scale, dissociating in the scale (in this case at the alloy-oxide interface) to form iron or chromium oxides. This path is considered to be

unlikely, unless the scale has significant, interconnected porosity.<sup>160</sup>

Path 5: which involves the dissociation of magnetite at the interface with the inner and outer layers,<sup>160,161</sup> with the iron ions released diffusing to the oxide-gas interface to react and form new oxide, and the released oxygen diffusing to the alloy-oxide interface to react with Cr in the alloy to form internal particles of  $\text{Cr}_2\text{O}_3$  (or Fe–Cr spinel).<sup>162</sup>

This whole area of steam oxidation has been reviewed recently by Wright and Dooley.<sup>162</sup>

### 1.22.8.2 Combustion Gases

A considerable amount of work has been carried out investigating the corrosion of steels in the gases produced during the combustion of fossil fuel due to

extensive use of low-alloy steels as heat exchanger tubes in power generation. Combustion gases contain many species, such as CO, CO<sub>2</sub>, SO<sub>2</sub>, SO<sub>3</sub>, H<sub>2</sub>S, and HCl, arising from elements within the fuel. The different combinations of operating temperature and chemical stoichiometry of combustion reactions lead to many possible complex corrosion reactions.

In coal-fired power stations, severe corrosion of the steam-generating tubes in the furnace walls has been attributed to reducing conditions with high  $p\text{CO}$ , low  $p\text{O}_2$ , high  $p\text{HCl}$ , and high local heat fluxes and flame impingement.<sup>163,164</sup> In areas of high corrosion, large concentrations of CO are almost always present, and thick Fe<sub>3</sub>O<sub>4</sub> scales, with islands and bands of FeS are observed.<sup>163,164</sup> Under the most severe reducing conditions, thick columnar scales of almost pure FeS have been observed.<sup>164</sup> The high corrosion rate areas are also subject to a significant flux of sulfur-bearing carbonaceous material in the flame envelope<sup>163</sup> which may locally exacerbate reducing conditions and raise the  $p\text{H}_2\text{S}$ .<sup>164</sup> Outside the high corrosion rate areas, the furnace atmospheres are found to be relatively O<sub>2</sub>-rich and the corrosion scales comprise protective Fe<sub>3</sub>O<sub>4</sub>.<sup>163</sup>

The emergence in recent times of biomass fuels intended to reduce the reliance on fossil fuels for steam power generation has introduced new challenges to the corrosion engineer. The use of biomass fuels based on a wide range of agricultural waste products, such as straw, forestry waste, sawdust, and purpose grown crops including coppiced willow and miscanthus have been investigated.<sup>165</sup> Concerns over potential high rates of metal wastage have been raised as the fireside environment is known to be particularly aggressive since it often contains HCl and different alkali salts which condense on heat exchanger surfaces promoting corrosion. Presently, it is necessary to operate biomass and energy from waste plants at lower temperatures than traditional coal fired systems so that tolerable corrosion rates prevail.<sup>166</sup> However, proposed methods of modifying combustion gas chemistry where corrosive KCl is converted to the far less corrosive K<sub>2</sub>SO<sub>4</sub> by the addition of sulphur may enable higher service temperatures to be attained.<sup>167</sup>

Similarly, refuse incineration plants are now based on the Waste-to-Energy concept, and it is necessary to optimize thermal transfer between combustion gases and water vapour. A significant problem with these installations concerns the fireside corrosion of the tubes. Combustion of waste generates highly corrosive flue gas often containing HCl, SO<sub>2</sub>, NaCl, KCl, alkali and heavy metal chlorides and

ashes containing chlorides and sulphates. *Wright and Krause*<sup>168,169</sup> predict corrosion by either combustion gases and/or molten deposits; erosion corrosion is also problematic due to flow rates and the presence of silica and alumina-silica particulates.

Fluidized-bed systems produce higher combustion intensities at lower temperatures than combustion of pulverized fuel in conventional fossil-fuel-fired boilers. The mineral matter for corrosion does not form fused salts and is not expected to release corrosive species. Fluidized bed combustors can, therefore, burn lower grade, cheaper fuel in smaller plant with better pollution control than traditional boilers.<sup>170</sup>

Minchener<sup>171</sup> reports that the bubble phase of atmospheric fluidized bed combustion has a  $p\text{O}_2$  in the range  $2 \times 10^{-1}$  to  $2 \times 10^{-2}$ . Combustion in the dense phase is substoichiometric, with the  $p\text{O}_2$  as low as  $10^{-13}$ , and SO<sub>2</sub> and SO<sub>3</sub> present in the range 500–5000 ppm. Low Cr–Mo steels show heavy scaling in these conditions, whereas 9–12% Cr steels show good resistance to sulfidation up to 650 °C. Roberts *et al.*,<sup>172</sup> however, report that for pressurized fluidized-bed combustion, ferritic steels at or below 9% Cr show heavy general corrosion above 540–560 °C.

### 1.22.8.3 Chemical Environments

The oil industry frequently uses stainless steels or exotic bonded alloys for the processing of crude oil in the temperature range 200–600 °C. These materials are very expensive and there is a strong economic incentive for finding cheaper alloys that are resistant to H<sub>2</sub>S and some gaseous organic sulfides arising from the S content of the crude oil.<sup>173</sup>

Metal sulfides show the same type of predominant defects as metal oxides, that is, cations in Fe<sub>(1-x)</sub>S, Cr<sub>(2+x)</sub>S<sub>3</sub>. The defect concentration in most sulfides is much higher than those in the corresponding oxides, but the defect mobilities are only slightly higher. Thus, the higher diffusivities and growth rates are determined by the higher defect concentrations. Cr and Al only slightly reduce the corrosion rate, and much higher Al is needed than that required for oxidation protection. Very protective scales are formed only at a S pressure lower than that for the formation of the base-metal sulfide.<sup>174</sup>

Mrowec *et al.*<sup>175</sup> examined the resistance to high temperature corrosion of Fe alloys with Cr contents between 0.35 and 74 at% Cr in 101 kPa S vapor. They found that the corrosion was parabolic, irrespective of the temperature or alloy composition, and noted

that sulfidation takes place at a rate five orders of magnitude greater than oxidation at equivalent temperatures. At less than 2% Cr, the alloys formed  $\text{Fe}_{(1-x)}\text{S}$  growing by outward diffusion of Fe ions, with traces of  $\text{FeCr}_2\text{S}_4$  near the metal core.

Narita and Nishida<sup>176</sup> examined the sulfidation of low Cr–Fe alloys at 700–900 °C in 101 kPa of pure S. They found that the addition of small quantities of Cr significantly decreased the corrosion rate because of the formation of  $\text{FeCr}_2\text{S}_4$  in the inner reaches of the scale. The scale comprised an outer FeS layer, with an inner layer of FeS,  $\text{FeCr}_2\text{S}_4$ , and  $\text{Cr}_3\text{S}_4$  in varying amounts depending upon the Cr content. The corners of specimens corroded more rapidly than flat faces because of breakaway conditions. At low Cr contents, the rate was increased, but above 4–6% Cr the parabolic rate constant decreased. Above 7.4% Cr, an intermediate layer containing  $\text{FeCr}_2\text{S}_4$  and varying amounts of  $\text{Cr}_3\text{S}_4$ , the proportion of the latter increasing with increasing Cr content, formed between the inner and outer layers.

In view of this potentially rapid degradation of Cr-containing steels by high temperature sulfidation in petrochemical and coal gasification reactors, Al is much used in the Fe alloys for these applications.<sup>177–180</sup> Al in Fe reduces the sulfidation rate in  $\text{S}_2$  vapor by up to two orders of magnitude<sup>181</sup> because of the high thermodynamic stability of aluminum sulfide relative to iron sulfide, the low rate of sulfidation of Al compared with pure Fe and the large PB ratio of  $\text{Al}_2\text{S}_3$  (3.7). The addition of 5% Al in Fe in 101 kPa  $\text{S}_2$  vapor between 500 and 700 °C resulted in the rate of reaction decreasing by a factor of 10. Parabolic kinetics were observed, with the inner layer of a duplex FeS scale containing a finely dispersed  $\text{Al}_2\text{S}_3$  phase which acts as a diffusion barrier to  $\text{Fe}^{2+}$  migration. Increasing the temperature to 800 °C resulted in a rapid take off of the corrosion rate, with catastrophic corrosion rates above 800 °C due to the large volume of  $\text{Al}_2\text{S}_3$  causing an increase in scale porosity.

Condit *et al.*<sup>182</sup> examined the sulfidation of several Fe–Cr–Al alloys under a variety of sulfidizing conditions. They noted that, in the early stages of sulfidation, a thin compact inner layer forms that is high in Cr and Al. Subsequently, a thicker microcrystalline outer layer forms with a uniform Fe, Cr, and Al composition. Formation of the outer compact layer was favored by increasing  $p\text{S}_2$  and decreasing temperature, with the layer forming much more rapidly in  $\text{H}_2\text{S}$  than in pure  $\text{S}_2$ . The sublayer disappeared more or less rapidly depending upon the alloy composition.

The authors propose three stages for scale development. First, a thin compact layer forms because of the penetration of S into the alloy with preferential formation of sulfide from those metals with the highest affinity for S.  $\text{Fe}_{(1-x)}\text{S}$  also forms because of the abundance of Fe in the alloy.

The outer layer then dissociates to release sulfur, which dissolves in the grain boundaries of the alloy to form Cr and Al sulfides. The Fe released by this dissociation sulfidizes again at the interface between the two layers. The volume increase associated with the conversion of metal to sulfide generates a mechanical stress that causes the outer layer to break up and permits permeation of S. This initiates a second stage, where growth of the scale is linear and comprises a porous outer layer, with FeS,  $\text{Cr}_2\text{S}_3$ , and  $\text{Al}_2\text{S}_3$  evenly distributed, possibly as  $\text{FeCr}_2\text{S}_4$ ,  $\text{FeAl}_2\text{S}_4$ , and  $\text{FeCr}_{(x)}\text{Al}_{(2-x)}\text{S}_4$ . S then diffuses through the pores to the scale–metal interface. The third stage comprises the formation of an outer compact layer of  $\text{Fe}_{(1-x)}\text{S}$  and continued thickening of the inner layer.

Addition of Cr to Fe–Al alloys aids the formation of Cr sulfides and  $\text{Al}_2\text{S}_3$ , which together markedly reduce the sulfidation rate.<sup>173</sup> Between 2% and 5% Cr then, more than 3% Al is required to obtain protection. At 9% Cr, however, only 1% Al is needed to give protection, since the Cr is sufficiently active to lower the S potential seen by Al (secondary gettering). Thus, all Fe–Cr–Al alloys initially form FeS, Cr sulfides, and  $\text{Al}_2\text{S}_3$ . The Cr and Al are then exposed to a much lower  $p\text{S}_2$  at the scale–metal interface and Cr sulfides and  $\text{Al}_2\text{S}_3$  grow preferentially if their activity is high enough. Ultimately, a protective layer of  $\text{Al}_2\text{S}_3$  or  $\text{Al}_2\text{S}_3$  + Cr sulfides develops at the scale–metal interface and the reaction rate decreases substantially.

Karlson *et al.*<sup>183</sup> found, from on-site experience of cement-producing plant, that corrosion of Fe surfaces may occur in gases containing  $\text{O}_2$ ,  $\text{SO}_2$ , and alkali chlorides such as NaCl and KCl between 300 and 500 °C. They reported that the corrosion rates may be extraordinarily high (5–10 mm month<sup>−1</sup>) implying liquid-phase corrosion. Laboratory simulation of the plant conditions demonstrated the need for both  $\text{SO}_2$  and the alkali chloride in the environment. The principal corrosion reaction was found to be

A thermodynamic evaluation of this equation indicated that the reaction could proceed with  $\text{SO}_2$  levels as low as 100 ppm.

#### 1.22.8.4 CO/CO<sub>2</sub>

Failures of mild steel components in Magnox reactors in the United Kingdom and Italy after approximately 5 years of operation alerted the world to the potential for breakaway oxidation of low-alloy steels in CO/CO<sub>2</sub> environments.<sup>95</sup> The CO<sub>2</sub>, 1% CO, 300 vppm CH<sub>4</sub>, 250 vppm H<sub>2</sub>O, 100 vppm H<sub>2</sub> environment used in CAGRs was selected on the need to minimize oxidation of the graphite reactor core and deposition of C from the coolant gas.<sup>184</sup> Corrosion rate tests of 15 000–20 000 h, in the limited range of conditions anticipated by the designers, showed that the maximum reduction in corrosion rate of ferritic steels in CO<sub>2</sub> at 600 °C is realized at around the 9% Cr level.<sup>185–187</sup> Therefore, 9Cr1Mo steel was chosen for the evaporator and primary superheater sections of the CAGR.<sup>185</sup> However, in the late 1960s, Taylor (reported in Holmes *et al.*) identified evidence for a significant change in the corrosion mechanism for 9% Cr steels at around 550 °C. This change could lead to rate inversion with increasing temperature in steels containing 0.7–0.8% Si, or breakaway in 0.4–0.5% Si steels.

Because of their importance to the nuclear power generation industry, these observations initiated a vast amount of research into the oxidation of low-alloy steels in CO/CO<sub>2</sub> environments. It is now clear that low-alloy steels exhibit three types of behavior when exposed to CO/CO<sub>2</sub>, that is, protective, transitional, and linear-breakaway (Figure 12), with the time to breakaway and the breakaway rate being of crucial importance in determining component life.

For mild and low-alloy steels in CO<sub>2</sub>, the first scale to form is a compact coarse columnar layer of

**Figure 12** Schematic diagram of stages of low-alloy steel oxidation in CO/CO<sub>2</sub>.

Fe<sub>3</sub>O<sub>4</sub>.<sup>188–190</sup> Growth of this layer is controlled by outward grain boundary diffusion of Fe ions.<sup>190–192</sup> The inward counter-current of vacancies is initially annihilated at the metal surface, but eventually vacancy condensation at the scale–metal interface gives decohesion, the scale develops microporosity, an inner layer grows within the space created by the departing metal ions and a duplex scale forms.<sup>193–195</sup> Then for Cr-containing steels, the protective scale comprises an outer, coarse columnar-grained magnetite layer and an inner, slightly porous, Cr-rich spinel of fine (0.1 μm) equiaxed grains.<sup>70,194,196</sup> As with low-alloy steels in other environments, the Cr is not mobile in the scale, but is oxidized *in situ*.<sup>195,196</sup> Studies have shown that the M<sub>3</sub>O<sub>4</sub> spinel nucleates at asperities on the surface and duplex growth is also known to be favored in the vicinity of inclusions and specimen corners.<sup>197</sup> Once initiated, the inner layer grows by inward diffusion of O, probably as CO<sub>2</sub>, down microfissures and micropores,<sup>17,136,196</sup> in both the lateral and vertical directions, until a complete layer is obtained.<sup>197</sup> The growth of this layer subsequently follows the parabolic rate law.

During this protective stage, decreasing the water and CO content of the gas appears to decrease the rate constant of Cr-containing steels,<sup>184</sup> but has little effect on the rate constant of carbon steels.<sup>193,198</sup> The rate constant of all steels has been found to decrease with decreasing temperature and increasing Si content.<sup>184,185,195,199</sup> Ferguson *et al.*<sup>198</sup> have also reported that increasing the S content of carbon steels reduces the parabolic rate constant.

An increase in the Si content of the steel has been reported to give a significant increase in the duration of the protective regime for carbon steel.<sup>188,200,201</sup> A similar benefit has also been reported for Cr-containing steels.<sup>193,198,202</sup> Increases in the duration of the protective regime are also realized with reductions in the CO and H<sub>2</sub>O contents of the gas,<sup>198</sup> in the temperatures,<sup>185,193,198</sup> and for carbon steels, in the surface roughness,<sup>193</sup> or for 9Cr steels, with increased surface cold work. Robertson and Manning<sup>43</sup> found that breakaway may also be delayed by some S-containing gases.

Following the initial protective period, under certain conditions of temperature, alloy and gas composition,<sup>185</sup> the oxidation goes through a transitional stage into breakaway. Several authors have reported that breakaway oxidation is initiated once the scale reaches a critical thickness<sup>184,185</sup> or weight gain<sup>70</sup> and only occurs below an initially protective duplex layer.<sup>43,195</sup> Both single-layer protective and duplex-layer

protective scales have a PBR of 2.1, whereas breakaway scales show a PBR of approximately 2.7, containing around 23% porosity,<sup>195</sup> and graphitic carbon grains (up to 6% by weight) between the oxide grains.<sup>193,198</sup>

During this transitional period, and once full breakaway is established, growth occurs throughout the oxide and close to the scale–metal interface.<sup>203</sup> Growth below the oxidant surface requires oxidant transport through the scale, but solid-state lattice diffusion is much too slow to account for the rates observed.<sup>17</sup> Therefore, a porous scale is required. Mechanisms for pore growth have been postulated by several authors<sup>204–207</sup> who have suggested that the transition from single-layer to duplex growth is due to the initiation of pores within the scale. Then breakaway was thought to be caused by increased porosity giving unlimited access of oxidant to metal surface. However Atkinson<sup>47</sup> has shown single layer scales to be slightly porous. Robertson and Manning<sup>43</sup> have proposed that oxidant access is always available and the type of scale that develops is dependent upon conditions at the scale–metal interface. Breakaway occurs if space is created by continuous scale deformation or creep.<sup>208</sup>

The inward penetration of CO<sub>2</sub> via cracks and micropores gives

2CO = O<sub>2</sub> + 2C via the Boudouard reaction

at the scale–metal interface.<sup>136,196</sup>

The carbon initially diffuses into the steel, but ultimately, the steel may become saturated with C.<sup>208</sup> There is no detectable solubility of C in FeO, Fe<sub>3</sub>O<sub>4</sub>, MnO, or Cr<sub>2</sub>O<sub>3</sub>,<sup>209</sup> and C can only permeate through pores or faulty scales.<sup>112</sup> Thus, the C then deposits at the scale–metal interface and prevents the formation of a coherent protective layer once it reaches a critical activity.<sup>208</sup> Carbides in the steel have been found to be the preferred sites for breakaway. These are either pre-existing carbides or carbides precipitated by C injection during oxidation.<sup>190</sup> Precarburized or graphite-painted steel breaks away rapidly, as do thin foils, because of the smaller C sink available.<sup>190</sup> Pritchard *et al.*<sup>89</sup> reported that the proportion of C in the scale increased with scale thickness and water content of the gas and was higher in breakaway oxide. For 9% Cr steel, breakaway oxidation is associated with heavy carburization of the metal and C deposition within the oxide, with preferential breakaway occurring at corners and edges.<sup>196</sup>

For Fe in CO/CO<sub>2</sub> at atmospheric pressure, Surman<sup>210</sup> found that if

$$10^{-3} < \frac{p\text{CO}}{p\text{CO} + p\text{CO}_2} < 0.3$$

then the oxidation is parabolic and very little C deposition occurs. He concluded that magnetite is not sufficiently catalytic to promote the Boudouard reaction unless CO > 10% and moisture is present and surmised that H<sub>2</sub>O promotes the formation of a Boudouard catalyst. If the CO is greater than 0.4 in this expression, oxidation and carbon deposition occur simultaneously at a linear rate.<sup>211</sup>

German and Littlejohn<sup>193</sup> have observed that increasing the Si content of carbon steel reduces the linear rate constant during breakaway and Banks and Lorimer<sup>208</sup> have shown that Cr and Si reduce the creep rate of Fe<sub>3</sub>O<sub>4</sub>, thus reducing the postbreakaway rate of Cr-containing steels. However, Si has been reported as having no effect on the postbreakaway rate on 9Cr steels.<sup>184,199</sup> Small changes to the CO and H<sub>2</sub>O content of the environment and the temperature have no significant effect on the breakaway rate constant, but a large reduction in the CO can cause reversion to protective kinetics,<sup>211</sup> as does reducing the CO<sub>2</sub> pressure to atmospheric.<sup>212</sup> Increasing the CO switches breakaway on again.<sup>211</sup>

### 1.23.1 Introduction

In industrial applications where high temperatures are required or produced, chromium-containing alloys are widely used. Based on iron and/or nickel,

and less often on cobalt, they can offer mechanical properties which can be adjusted to the situations they will encounter, with additional resistance to chemical attack by the various gaseous atmospheres.

Over the years, there have been arguments about who invented stainless steels, the first chromium-containing alloys. It seems that Pierre Berthier in France was the first to report ~1820 that addition of sufficient chromium to iron suppressed attack by water and acids. However, he could not, at that time, produce mechanically resistant steels. Harry Brearley of Sheffield was the first to produce a 13% Cr–0.24% C martensitic stainless steel in 1913 and to observe its excellent resistance to corrosion. It is amazing to note that this discovery was made as Brearley looked for better erosion (and not corrosion) resistance of gun barrels. More interesting is that his work was made in a technical laboratory cofinanced by two main Sheffield steel companies of the day. It seems however that the Krupp German company in Essen (first austenitic stainless steel patent: 1912) as well as Swedish steel-makers produced stainless steels at this time. In fact, all industrial countries could produce such materials after World War I. In 1924, grade 304 (18Cr–8Ni) was produced at Sheffield by W. H. Hatfield.

Concerning nickel based alloys, they were developed a decade later, for example, by Haynes International, USA. The term Superalloy appeared just after World War II for designing new alloys for aircraft engine applications.

Cobalt based alloys were also first produced at the beginning of the twentieth century, for example, by Stellite in 1907 in Canada.

The first published systematic comparative study of the behavior of numerous chromium-containing alloys by Hatfield appeared in the *Journal of the Iron and Steel Institute* in 1927.<sup>1</sup>

The same author published the first quantified values in 1928, using a 'scaling index' (SI) defined as the temperature giving a certain weight gain (in  $\text{g m}^{-2}$ ) at the end of a seven 6-h cycle oxidation run.<sup>2</sup> The higher the SI, the better the behavior of the alloys. His results for  $\text{SI}_{10}$  ( $10 \text{ g m}^{-2}$ ),  $\text{SI}_{20}$  ( $20 \text{ g m}^{-2}$ ), and  $\text{SI}_{100}$  ( $100 \text{ g m}^{-2}$ ) are presented in Table 1.

Nowadays, many results can be found either in the scientific literature or in technical notes provided by the steelmakers, giving the maximum service temperature acceptable for all commercial alloys. Figure 1 presents such data for isothermal oxidation

in air; it is generally considered that this maximum service temperature must be reduced by at least  $25^\circ\text{C}$  in cycling conditions, sometimes by larger values in more aggressive atmospheres (metal dusting or sulfidizing environments).

At present, simple scientific principles can explain the results of Hatfield; they are recalled in the following section.

### 1.23.2 Underlying Principles of High Temperature Corrosion Protection by Chromium

High temperature alloys must be protected in service by an external slow-growing oxide scale. In the case of chromium-containing alloys, this protective scale is based on chromia  $\text{Cr}_2\text{O}_3$ .

#### 1.23.2.1 Various Types of Chromium-Containing Alloys

As may be observed on Fe–Cr, Ni–Cr, and Co–Cr binary system phase diagrams (Figures 2–4),

**Table 1** Scaling indexes ( $^\circ\text{C}$ ) for a series of chromium-containing alloys

Oxidizing atmosphere: combustion gas with 50% excess air.

**Figure 1** Maximum isothermal service temperature for various chromia-forming alloys, estimated from literature and producer data.

**Figure 2** Fe-Cr phase diagram.

**Figure 3** Ni–Cr phase diagram.

**Figure 4** Co–Cr phase diagram.

chromium is a highly soluble element in iron, nickel, and cobalt.<sup>3</sup> However, the intermetallic sigma phase may appear during long time anneal of iron–chromium alloys at medium temperatures

(700–1100 K), with very bad mechanical properties (high brittleness) and its formation must be avoided. Ternary or quaternary Fe–Ni–Co–Cr solid solutions are also stable.

The particular situation of iron, where bcc–fcc allotropic transformation occurs at 912 °C, has to be considered. Increasing chromium content of bcc Fe–Cr alloys to 5 wt% first reduces this value to ~850 °C before increasing it to ~1050 °C for 15 wt%. For higher Cr contents, the steels retain the bcc structure up to the melting temperature. Fe–Cr ferritic stainless steels with a chromium content falling in the  $\gamma + \alpha$  loop, if not ‘stabilized,’ undergo phase transformation on heating, leading to a biphasic structure. As described in the following, the appearance of the fcc  $\gamma$  phase significantly modifies two main properties of the alloy: diffusion coefficient of chromium and coefficient of thermal expansion (CTE).

Nickel is used as  $\gamma$ -promoter in chromium alloys, giving better mechanical properties than the ferritic structure. Considering not only the high price of nickel, but also the instability of its market, efforts have been made to replace it by other gamma-stabilizing elements. Manganese-containing austenitic stainless steels, such as 204Cu grade, have been produced and tested in high temperature situations.<sup>4</sup>

Carbon and nitrogen minor elements in Fe–Cr alloys are  $\gamma$ -stabilizers. Their concentration is therefore not strictly limited in austenitic alloys and can be adjusted according to the destination of the materials. Conversely, their amounts must be controlled in ferritic steels.

Metallic elements such as Ti, Nb, Mo, intrinsically ferrite promoters, have the additional property to strongly fix carbon and nitrogen as carbides, nitrides, and carbonitrides. Due to this fact, they increase the stability domain of ferrite and are largely used in ‘stabilized’ ferritic stainless steels.

Regarding these considerations, high temperature chromium-rich alloys are generally described as martensitic steels (iron based, with ferritic structure), stainless steels (iron based, with ferritic or austenitic structure) and refractory alloys (iron, nickel, or cobalt based, with austenitic structure).

Martensitic low chromium steel grades are first hardened by rapid cooling, and then tempered at a temperature in excess of the proposed service temperature. They are largely used for pressurized water or steam tubes, vessels and heat exchangers. Initially, based on the composition Fe–2.25Cr–1Mo (T22 steel), these grades had to follow the regular increase in temperature and pressure of processes to fit the required decrease in CO<sub>2</sub> emissions; they now include 9% Cr (T9 steel) and several similar grades with minor additions that increase their creep resistance in service (steels T91, T92, T911).

Chromium steels containing 12% Cr and more are usually qualified as stainless steels. Commercial grades are 12% and 17% Cr, with a new composition recently appeared at 14%. Higher chromium is also available, up to 30%. These alloys are ferritic or austenitic depending on the fraction of  $\gamma$ -stabilizing element (Ni or Mn). Both ferritic and austenitic stainless steels are protected in high temperature service by a chromia scale. However, that does not mean they can be used indifferently in any industrial situation. Austenitic stainless steels are preferably used when mechanical resistance at high temperatures is required, despite their higher price. Conversely, ferritic grades are used in situations where permanent or cyclic mechanical loading in service remains low. However, a careful design of parts made of ferritic grades may authorize their use in various industrial situations.

Due to their difference in crystallographic structure, ferritics, and austenitics do not allow identical chromium diffusion rates; the more open bcc ferritic structure allow quicker chromium diffusion than the compact fcc austenitic structure. As a result, alloy chromium depletion under chromia scales will be more marked, but to shorter depths, in austenitics.

A second property which makes ferritics and austenitics different is their CTE, which lies in the range  $(12\text{--}13) \times 10^{-6} \text{ K}^{-1}$  for the bcc grades and  $(19\text{--}20) \times 10^{-6} \text{ K}^{-1}$  for the fcc grades. Due to the lower CTE of chromia  $((8\text{--}12) \times 10^{-6} \text{ K}^{-1}$  according to various authors), chromia scales grown on austenitic stainless steels are subjected to more intense compressive stresses on cooling than the same scales on ferritics.

A particular phenomenon occurring during temperature increase (decrease) of the nonstabilized ferritic grades is the volume increase (decrease) associated with the ferrite–austenite transformation which can be deleterious for the integrity of the oxide scale, producing early breakaway corrosion in thermal cycling conditions.

Refractory alloys contain high chromium levels and strengthening elements to increase their mechanical properties at high temperatures. Based on the austenitic structure, they are mainly Fe or Ni-rich, and less often Co-rich.

### 1.23.2.2 Growth of Cr-Containing Oxides

To discuss the behavior of the various chromia-forming alloys used in high temperature industrial applications, several physical, chemical, and

mechanical mechanisms are of importance. Although they have been mostly described in other chapters, they are briefly recalled here for an efficient reading of this chapter.

### 1.23.2.2.1 Chromia growth

Regarding M–Cr–O systems (M = Fe, Ni, Co) subjected to oxidizing atmospheres, chromia  $\text{Cr}_2\text{O}_3$  is the most stable oxide. It is therefore expected to inhibit M oxidation by creating a chromia barrier to oxygen, lowering the oxygen chemical potential in contact with the alloy to a value too low for oxidation of the major element M. In fact, the minimum chromium content for effectively growing a chromia scale is  $\sim 14\%$  for iron, 20% for nickel, and 25% for cobalt.<sup>5</sup> Chromia is regarded as an amphoteric semiconductor, with predominant chromium interstitials at low oxygen potentials (i.e., near the metal–oxide interface) and predominant chromium vacancies at higher oxygen potentials (i.e., near the oxide–gas interface).<sup>6</sup> In all situations where chromium alloys are oxidized in air, chromia growth takes place by chromium transport through the scale. Inversion of transport may occur by blocking cation diffusion using yttrium or rare earth trace additions to the alloys, resulting in slower growth by oxygen transport (reactive element effect, REE). Water vapor or steam atmospheres also produce chromia scales where inward transport of H-assisted oxygen is predominant.<sup>7</sup>

Due to the high compactness of chromia, and also due to the necessity for less oxidizable Fe and Ni elements to enter it in the atomic state (atomic radius  $\sim 125$  pm compared to ionic (+II) radius  $\sim 77$  pm), this oxide is a good diffusion barrier for these major elements of stainless steels and refractory alloys. Conversely, Mn, Ti and, to a lesser extent, Nb, which are more oxidizable than chromium, rapidly diffuse through chromia scales as small cations ( $r_{\text{Mn}^{2+}} = 80$  pm,  $r_{\text{Ti}^{4+}} = 68$  pm).

The behavior of iron also has to be considered, as  $\text{Fe}^{3+}$  and  $\text{Cr}^{3+}$  ions are completely exchangeable in the rhombohedral chromia structure. All range of solid solutions between  $\text{Fe}_2\text{O}_3$  (hematite) and  $\text{Cr}_2\text{O}_3$  (chromia) are known, with the general formula  $\text{Cr}_{2-x}\text{Fe}_x\text{O}_3$ . In high temperature processes, it is of importance to limit the values of  $x$  to the minimum by rapidly heating the steels to 800 °C or using a reducing atmosphere for hematite during heating. This is of particular importance when iron-free surfaces are needed, for example, in the petrochemical industry where iron catalyzes graphite deposition (catalytic coking).

Maintaining protection against oxidation necessitates that chromia scales remain compact and adherent to the alloy substrates. Understanding the mechanisms of scale spallation was the subject of much work in the past decades.<sup>8,9</sup> Many results of stress measurements appear in the literature, showing mean values of 1–3 GPa compressive stresses in chromia scales, counterbalanced by tensile MPa values in the alloy substrates. However, it was experienced that oxide stress is not the key parameter in scale spallation, but that scale adhesion energy, defined as the metal–oxide interfacial fracture energy, was of greater importance.<sup>10</sup>

### 1.23.2.2.2 Growth of spinel phases

In any situation where a chromia scale cannot grow or be maintained on any Fe-containing alloy surface, magnetite enriched in chromium becomes the major oxidation product. This compound exhibits less protective properties than chromia, allowing outward transport of iron and inward transport of oxygen. That results in a typical duplex morphology where the external subscale is chromium free (hematite or magnetite) and the internal one has the limit stoichiometry of  $\text{FeCr}_2\text{O}_4$  (chromite spinel phase).

Iron chromite affords lower protection against oxidation compared to chromia, with larger mobility of oxide ions leading to more internal oxide growth.

Nickel–chromium spinel (nickel chromite  $\text{NiCr}_2\text{O}_4$ ) formation may occur concurrently with chromia on nickel based low chromium alloys, leading to some loss of protection. Increasing chromium content in the alloy tends to suppress this formation.

Manganese–chromium spinel (manganese chromite,  $\text{Mn}_{3-x}\text{Cr}_x\text{O}_4$ , with  $x$  generally between 1.5 and 2) is known to constitute the external part of the scale grown on high temperature alloys containing fractions of manganese, as low as 0.5%. This oxide overlays the internal chromia part of the scale and is the result of manganese diffusion from the alloy through this chromia part. The formation of this oxide is not considered as deleterious as it remains generally compact and adherent and it was even claimed that it is better resistant than chromia to chromium carbide transformation in high carbon activity atmospheres.<sup>11</sup> It also decreases chromia activity and consequently inhibits chromium (VI) vaporization.<sup>12,13</sup>

Competition between chromia and iron–nickel chromite is sometimes a key factor for long lasting use of high temperature alloys. Catastrophic break away oxidation occurs generally by local than by

generalized transformation of chromia to a spinel phase.<sup>14,15</sup> Factors that promote spinel appearance are

- high temperatures,
- low chromium and/or subsurface dechromization,
- thermal cycling, and
- water vapor atmospheres.

Promoting chromia growth may be obtained by increasing the chromium content of alloy or by any chemical or mechanical operation that enhances the number of fast diffusion paths for chromium from the alloy to the metal–oxide interface: laser glazing induced microcrystallization or work hardening generating high concentration of dislocations.

### 1.23.2.3 Influence of Alloy Minor Elements

Properties of today's industrial chromia-forming alloys are tailored to their exact application by adjusting the amount of minor metallic (Mn, Ti, Nb, Mo, Y, La, Ce, Zr) or nonmetallic (C, S, Si, B) elements.

The effect of manganese was described above. Titanium, in the form of carbide, nitride, carbonitride, and eventually excess solid solution Ti, slightly increases the parabolic rate constant of oxidation, but concurrently promotes scale adhesion,<sup>16</sup> due to TiO<sub>2</sub> precipitation at the alloy–scale interface. External diffusion of titanium through chromia may also occur, forming titania and/or Cr<sub>2</sub>TiO<sub>5</sub> surface nodules. Niobium in the form of carbide, nitride, carbonitride, but also of Fe<sub>2</sub>Nb intergranular intermetallic precipitates, may slowly oxidize to NbO at the alloy–scale interface and also slowly diffuse to the scale surface, forming NbO<sub>2</sub> (in solid solution with TiO<sub>2</sub> when this latter element is present). Molybdenum is not oxidized at the alloy–chromia interface, remaining as an intermetallic phase. Silicon and boron, more oxidizable than chromium, enrich as oxides at the metal–scale interface. Sulfur also segregates at this interface in the elementary form, strongly reducing scale adhesion.<sup>17</sup> Reactive elements (Y, La, Ce, Zr) decrease oxidation rates and promote scale adhesion. Mechanisms for that have been discussed at length. Interface sulfur removing and scale growth inversion are probably of major importance in these beneficial phenomena.

### 1.23.3 High Temperature Oxidation Behavior of Chromium Alloys

Oxidation, in its original meaning of oxygen fixation, is the most frequently encountered mode of high

temperature corrosion. All furnace elements working in air or combustion atmospheres are subject to oxide scale growth. It should be noted that oxidation, generally considered as a degradation mechanism, may be used as a beneficial phenomenon, as in stainless steel processing where iron–chromium thick scales formed during reheating before hot rolling consume surface defects and form a ductile lubricating coating preventing sticking between the metal and the roller.

#### 1.23.3.1 Oxidation of Martensitic and Ferritic Stainless Steels

Martensitic grades are possibly chromia-formers in oxygen or air in low aggressive conditions, but exhibit rapid chromia destabilization with increases in temperature and time. This destabilization, leading to the so-called breakaway corrosion, is also accelerated by thermal cycling. Post-breakaway scales exhibit classical duplex morphology, with internal Cr-containing magnetite subscale and external hematite. In water vapor or steam, chromia destabilization is easier and these grades can no longer be considered as chromia-formers. Duplex iron-rich scales are observed, as in air, generally with external magnetite instead of hematite due to low values of the oxygen chemical potential in the steam environment. For such a steam situation, an empirical law was proposed by Gabrel *et al.*<sup>18</sup> for the parabolic increase of scale thickness  $\zeta$

$$\zeta^2 = (8.099)^2 \times 2.35 \cdot 10^{10} \exp \left[ -\frac{16200}{8.32T} \right] (1 - \text{Si})^{187} (1 - \text{Cr})^{36.7} t$$

High chromium ( $\geq 18\%$ ) ferritic stainless steels (AISI 4XX grades) oxidize with near-parabolic slow growth of chromia-rich scales. The Fe/Cr ratio of the rhombohedral oxide increases with increasing temperature and oxidation time. For these grades, passive chromia scales can form for long periods, giving excellent oxidation resistance. As a consequence, increasing chromium concentration confers better oxidation resistance in isothermal conditions, as observed in [Figure 5](#). It is noted that small aluminum additions to ferritic stainless steels generate internal precipitation of alumina between the steel substrate and the chromia scale, leading to strong improvements in the oxidation behavior, as shown for the 12SR (12Cr–1Al) and 18SR (18Cr–2Al) in [Figure 5](#). Such alloys

are chromia-formers in air, but may become exclusively alumina-formers in high temperature situations of decreased oxygen chemical potential where chromia becomes unstable. Ferritic FeCrAls, exclusively alumina-formers need a minimum composition of 20Cr–4Al.

**Figure 5** Weight gains of various stainless steel grades after 100 h isothermal oxidation in air (data from producers).

**Table 2** Time to breakaway for cyclic oxidation of ferritic stainless steels (in and out 20 min cycles in laboratory air at 950 °C)

Steel grade	409	439	441	436
Composition	12 Cr	18 Cr	18 Cr–Ti, Nb	18 Cr–1 Mo
Time to breakaway (h)	150	900	>1200	>1200

**Table 3** Calculated partial pressures of gaseous chromium (VI) oxide or oxyhydroxide in equilibrium with solid  $\text{Cr}_2\text{O}_3$  or  $\text{MnCr}_2\text{O}_4$

Atmosphere	Solid compound	Predominant gas	900 (K)	1200 (K)	1500 (K)
$\text{N}_2 + 20\% \text{O}_2$	$\text{Cr}_2\text{O}_3$	$\text{CrO}_3$	$1.5 \times 10^{-8}$	$1.4 \times 10^{-6}$	$3.3 \times 10^{-5}$
$\text{N}_2 + 20\% \text{O}_2$	$\text{MnCr}_2\text{O}_4$	$\text{CrO}_3$	$5.0 \times 10^{-10}$	$1.1 \times 10^{-7}$	$4.3 \times 10^{-6}$

In thermal cycling situations, good protection is obtained up to MICF (mechanically induced chemical failure), as proposed by Evans,<sup>19</sup> where breakaway oxidation occurs by forming nonprotective iron-rich oxides. In such thermal cycling situations, the same beneficial influence of chromium was noted, with also clear improvement by the ferrite stabilizers Ti and Nb (Table 2).<sup>20</sup> The 441 grade is commonly proposed for exhaust parts in the automotive industry.

High temperatures or water vapor in the gas may promote chromium (VI) oxide or oxyhydroxide volatilization, strongly impeded by manganese additions which form an external  $\text{MnCr}_2\text{O}_4$  spinel phase, decreasing chromium (III) oxide activity and therefore the gaseous chromium (VI) compound's partial pressure as seen in Table 3.

The growing interest in solid oxide fuel cells (SOFCs) working at intermediate temperatures (<800 °C) has led to increasing work on ferritic stainless steels which are possibly used as interconnectors, separating the cathode side (air) from the anode side (wet hydrogen) of the cell. Good technical solutions need decreased chromium (VI) poisoning of the cathode and manganese additions help by lowering the partial pressure of undesired gas species. Another important parameter for this application is the low contact resistance between scale and metal and elements forming internal oxide enrichment at the metal–scale interface (mainly Si and Al) must be avoided. Following these observations, special grades to be used in SOFCs have been produced and are now available in the market (Table 4).

### 1.23.3.2 Oxidation of Austenitic Stainless Steels (AISI 3XX Grades)

For temperatures lower than 800 °C, 18Cr–8Ni stainless steels 304 and 321 are commonly used. Increasing

**Figure 6** Isothermal air behavior of various austenitic grades compared to three ferritics with equivalent chromium contents; legend: Cr/Ni in wt%. Redrawn from Brasunas, A. de S.; Gow, J. T.; Harder, O. E. *Proc. ASTM* 1946, 46, 870.

service temperature needs increased chromium up to 20–25%, with larger silicon additions up to 2–2.5% producing silica enrichment at the alloy–chromia interface, decreasing chromium incorporation into the scale. With such compositions, grades 309, 310, and 314 are known as ‘refractory stainless steels.’ All these grades are more mechanically resistant than ferritics and can be further strengthened by increasing carbon and/or nitrogen contents.

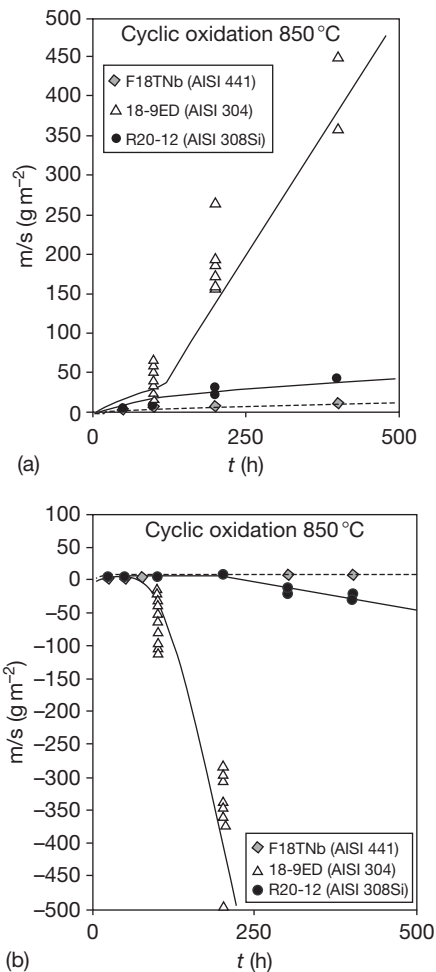

Care must be taken when using high chromium austenitic grades at intermediate temperatures where  $\sigma$ -FeCr may precipitate (310, 314, 253 MA grades, for example), leading to brittleness. Possible formation of this phase can be roughly predicted from the Fe–Ni–Cr phase diagram, with additional influence of minor elements by using empirical relations.<sup>24</sup>

In **Figure 6**, it is shown that the austenitic grades are more scaling resistant in isothermal conditions than the ferritic ones for equivalent chromium content.

In cyclic conditions, heavy spallation is observed clearly due to strong differential contraction on cooling. Here also, increasing nickel content leads to better behavior (**Figure 7**).

**Figure 7** Weight loss in cyclic conditions (15 min heating at 980 °C, 5 min cooling) of austenitic grades with different chromium and nickel contents. Adapted from Lai, G. A. *High Temperature Corrosion of Engineering Alloys*; ASM International: Metals Park, OH, 1990.

An influence of steel structure on spallation appears also in the recent results from a study by Ugine & ALZ (today ArcelorMittal Stainless Europe) for exhaust systems (**Figure 8**),<sup>25</sup> confirming older results (**Table 5** and **Figure 9**) showing that ferritic stainless steels are better resistant in short cycle situations than austenitic ones. This is due to a lower thermal expansion coefficient which prevents high stress states from appearing during cooling. Ferritic materials also relax by high temperature creep, further decreasing oxide stress. However, the good behavior of ferritic stainless steels in cyclic conditions is lost as soon as they are used at temperatures entering the ( $\alpha + \gamma$ ) domain.

Internal alumina precipitation for the 18SR grade is also beneficial as seen in **Table 5**.

### 1.23.3.3 High Temperature Oxidation of Ni- and Co-Containing Alloys

#### 1.23.3.3.1 Ni-Cr alloys

Binary nickel–chromium alloys have been recognized very early as high temperature oxidation resistant. **Table 6** summarizes results published in 1957 showing the ability of Cr to drastically decrease the parabolic rate constant of nickel oxidation.<sup>28</sup> It can be noted that higher chromium is necessary when the temperature increases. Commercial alloys mainly contain 20–30% Cr to stabilize a protective chromia scale and always contain several minor additions to improve their mechanical and/or chemical properties: typical ‘Nichrome’ (UNS N06003, EN/DIN 2.4869) contains 1% Si and

**Figure 9** Cyclic oxidation weight change of several ferritic and austenitic stainless steels after 400 cycles in air at 1000 °C (30 min in furnace, 30 min out). Reproduced from Kado, S., Yamazaki, T., Yoshida, K., Yabe, K., Kobayashi, H., *Trans. Iron Steel Inst. Jpn.* **1978**, 18, 387.

0.01–0.04 reactive element, whereas Nimonic 75 contains 0.5% Ti.

Nickel–chromium alloys are mainly used in the form of wires for electrical heating and for making heat resistant parts in situations where mechanical considerations are low.

### 1.23.3.3.2 Ni–Fe–Cr alloys

Increasing nickel content from stainless steels stabilizes the gamma phase and prevents sigma phase formation. High mechanical resistance, particularly to creep in service, is realized by adding interstitial nonmetallic elements (C, N, B) and/or substitutional refractory elements (Mo, W, Ta, Nb) in solid solution in the  $\gamma$  phase. Carbide or intermetallic precipitation also participates in alloy strengthening.

Other effects of minor element additions are to slow down grain growth in service, to inhibit sigma phase formation and to lower the thermal expansion coefficient. **Figure 10** shows that Ni-base alloys (600, X, and 230) have naturally lower CTE than Fe-based (304, 800H) and also that the strongly-charged 230 alloy (14% W, 2% Mo) has lower CTE than Alloy X (9% Mo) and alloy 600 (no W, Mo). Decreasing CTE enhances resistance to scale spallation in thermal cycling service.

Scaling resistance of nickel-based alloys in oxidizing atmospheres is far better compared to stainless steels (**Figure 11**) and these grades are of major importance in all very high temperature processes using furnaces or combustion chambers for energy transformation and chemical or metallurgical reactions.

### 1.23.3.3.3 Co–Cr alloys

Industrial cobalt–chromium alloys are strengthened by solid solution and carbide formation. They present very good resistance to high temperature creep, even for temperatures above 1000 °C. Due to their high

**Figure 11** Metal loss plus average internal penetration measured on various iron- and nickel-base alloys after 1008 h under flowing air ( $213.4 \text{ cm min}^{-1}$ ). Metal loss from weight gain, penetration from cross-section observations. Samples cycled to room temperature once a week. Asterisk: actual value larger. Data from Haynes International.

**Figure 12** Comparative oxidation damage of one nickel- and one cobalt-based alloy of approximate identical composition showing better performance of the nickel alloy at the highest temperatures.

chromium contents, they also resist oxidation well, but it was reported that alloy 188 is sensitive to water vapor in the oxidizing atmosphere which reduces its life time. They are of interesting use when nickel is prohibited, for example in sulfidizing situations where Ni-containing low melting temperature eutectics can form.

The drawback is that their market price is high. When no particular situation imposes the choice of cobalt, it seems preferable to use nickel alloys as shown in Figure 12.

**Figure 13** Cross section of alloy HK40 oxidized at  $1100^\circ\text{C}$  in air for 50 h, showing large internal penetrations.

#### 1.23.3.3.4 Various comparisons between alloy grades

One point which may be emphasized concerns the high concentrations of minor oxidizable elements, particularly for Ni(Co)–Cr grades, which lead to internal inter- and intragranular oxidation to depths often much larger than the chromia scale thickness (Figure 13). This may be deleterious for the mechanical resistance of these alloys in situations where the total weight gain seems to be not catastrophic. For engineering comparison between different grades, figures concerning metal loss or scale thickness must necessarily be discussed together with the depth of the affected metal (Table 7).

As seen earlier, it is difficult to compare the resistance to high temperature oxidation of various industrial grades using only one parameter. Trying to overcome this difficulty, an important work done at NASA was presented by Barrett where not only kinetics were taken into account but also the visual aspect of the samples.<sup>27</sup> Many industrial alloys were submitted to 10 cycles of 1000 h each at  $982^\circ\text{C}$  in air. Kinetics were evaluated by determining linear ( $k_l$ ) and parabolic ( $k_p$ ) rate constants from weight change measurements according to

$$\Delta m/A = k_l t + k_p t^{1/2}$$

The attack parameter, called  $\text{KB}_3$ , was defined by

$$\text{KB}_3 = k_p + 100|k_l|$$

for positive values of  $k_p$ , or by

$$\text{KB}_3 = 250|k_l|$$

for negligible or negative values of  $k_p$ .

<sup>a</sup>Porosity formation in the metallic substrate.

In addition to  $KB_3$ , the post-test appearance of samples was ranked from 1 to 5:

rank 1: excellent,  
rank 2: good,  
rank 3: fair,  
rank 4: poor,  
rank 5: catastrophic

and the global rating parameter ( $KB_4$ ) was defined by

$$KB_4 = KB_3[1 + 0.1(\text{rank} - 1)]$$

Using this global parameter, the behavior of alloys in long term thermal cycling situations was ranked according to the following rule:

- $KB_4 > 0.2$ : excellent
- $0.2 < KB_4 < 0.5$ : good
- $0.5 < KB_4 < 1$ : fair

- $1 < KB_4 < 5$ : poor
- $KB_4 > 5$ : catastrophic.

The results for Fe-, Ni-, and Co-chromium containing alloys appear in [Figures 14–16](#) respectively.

None of the iron-base alloys were ‘excellent,’ with only four in the ‘good’ range. A minimum of 20% Cr seemed necessary for this ‘good’ ranking. Nickel-base alloys behave better, with four grades in the ‘excellent’ family and nine in the ‘good’ one. It should be observed that Hasteloy-S, which behaved the best, contains the reactive element (La) that improves scale adhesion, but Chromel-A, having a quite similar  $KB_4$ , does not. In fact, this test exhibiting very long isothermal periods and only a few thermal cycles was probably not discriminating in terms of scale spallation. Cobalt-base alloys presented the best behavior, with five alloys out of

**Figure 14** KB<sub>4</sub> parameter for various iron-base chromia-forming alloys.

**Figure 15** KB<sub>4</sub> parameter for various nickel-base chromia-forming alloys.

eight tested ranking 'good' to 'excellent.' They all have high chromium content (25–28%). MAR-M-509 alloy, with 23.5% Cr has a 'fair' behavior probably due to 7% W and both alloys with lower chromium and higher W (WI-52 and L-605, 21Cr–11W and 20Cr–15W respectively) behaved 'catastrophic' and 'poor.'

It has to be reminded that the proposed test was performed at 982 °C, a temperature where chromia volatilization was not detrimental. The observation of the complete set of results also showed that alumina-forming alloys behaved much better than chromia-forming alloys, with 10 grades showing  $KB_4 < 0.1$ .

**Figure 16** KB<sub>4</sub> parameter for several cobalt-base chromia-forming alloys.

**Figure 17** Comparative metal penetration (metal loss + internal oxidation) of various alloys after 1 year oxidation in air as proposed by the ASSET system. Reproduced from John, R. C.; Pelton, A. D.; Thomson, W. T.; Young, A. L.; Wright, I. G. *High Temperature Corrosion Materials Chemistry III*. Electrochemical Society Meeting, March 25–30, 2001, Washington, DC, USA.

Another attempt to present comparative sets of results was initiated by SHELL under the name 'ASSET' (Alloy Selection System for Elevated Temperatures), in collaboration with several industrial and academic organizations in five countries.<sup>28</sup> This information system proposes a compilation of high temperature corrosion data, from literature and from specific testing, arranged so that engineering decisions can be made on lifetime, maximum temperature and influence of gas composition. In Figure 17 is presented the oxidation behavior of six common alloys exposed to air for 1 year. It is remarkable that, except the two ferritics (9Cr, 1Mo, and 410), all alloys behave similarly at 800 °C. Major differences are found at the lower and higher test temperatures,

with the worst alloys at 500 °C behaving the best at 1100 °C.

Attention has to be paid to transposition of oxidation data from laboratory tests to industrial practice. Alloys exposed in service to combustion atmospheres are better tested in burner rigs, a procedure really aggressive due to high rates of gas flow and possible particle impact. **Figure 18** shows comparative data from burner and furnace testing for various Fe-, Ni-, and Co-base alloys. It is clear that burner oxidation is more severe than still air by a factor extending from

**Figure 18** Metal loss and average metal penetration for various alloys exposed to still air oxidation (980 °C, six 1-week cycles, conditions of **Table 7**) and burner test rig at 980 °C for 1000 h. Data from Haynes International.

3–5 for the best alloys to 15–40 for the worst ones. However, the general ranking of alloys established by furnace testing is not strongly modified.

### 1.23.4 Concluding Remarks

The number of technical chromia-forming alloys proposed on the market is very large (see **Appendices 1–6**) and the choice of the right material is generally very difficult. The first step to a right choice is the careful observation of the service conditions which will be supported by the alloy, with clear definition of the possible accidental situations. To select the best grade, laboratory tests have to be performed at a temperature and in an atmosphere as close as possible to the real ones, taking into account possible thermal cycling. Comparison with specimens exposed to the real industrial situations may validate the laboratory tests.

Attention has also to be paid to the desired shape, as all alloys are not available in all shapes, and sometimes, the shape influences the corrosion resistance.

The cost of the material is also an important parameter, and the technical engineers must always decide whether they want to use an expensive alloy which will function for a long time or a cheaper one which will have to be replaced after limited service.

A last criterion to have in mind is the availability of the chosen grade, which must be rapidly delivered and possibly by several suppliers to avoid a monopoly situation.

### Glossary

**B2** Crystal structure formed by NiAl and FeAl (see [Figure 1\(a\)](#)).

**Corundum** Crystal structure formed by  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>.

**D0<sub>3</sub>** Crystal structure formed by Fe<sub>3</sub>Al (see [Figure 1\(d\)](#)).

**D0<sub>19</sub>** Crystal structure formed by Ti<sub>3</sub>Al (see [Figure 1\(e\)](#)).

**Hot corrosion** Corrosion in a high temperature environment where molten salts are present.

**Kirkendall effect** Vacancy formation in a diffusion couple because of differences in the interdiffusion coefficients of the two atoms.

**Laves phase** Intermetallic crystal structure.

**L1<sub>0</sub>** Crystal structure formed by TiAl (see [Figure 1\(b\)](#)).

**L1<sub>2</sub>** Crystal structure formed by Ni<sub>3</sub>Al (see [Figure 1\(c\)](#)).

**Pack cementation** Chemical vapor deposition process performed in a packed bed.

**Rutile** Crystal structure formed by  $\text{TiO}_2$ .

**Spinel** Crystal structure formed by  $\text{NiAl}_2\text{O}_4$  and other mixed oxides.

**X-phase** Mixed titanium–aluminum oxide phase.

**Z-phase** Mixed titanium–aluminum oxide phase.

## Abbreviations

**CVD** Chemical vapor deposition

**NCP** New cubic phase (formed in Ti–Al–O system)

**TBC** Thermal barrier coating

**TCP** Topographically close packed (phases)

**TGO** Thermally grown oxide

## 1.25.1 Introduction

Metal alloys, such as those discussed in the chapter on **High Temperature Corrosion of Alumina-forming Iron, Nickel and Cobalt-base Alloys** can be strengthened by the formation of intermetallic compounds, but alloys consisting entirely of intermetallic compounds are stronger. These intermetallic compounds typically have higher melting temperatures compared with their constituent metals, and are thus attractive materials for high temperature applications. The most widely used intermetallic compounds for high temperature applications are aluminides, because of their low densities and their ability, or at least potential, to form a protective alumina scale. Silicides are also used for some high temperature applications, but their oxidation behavior is similar to that of nonoxide ceramics, such as silicon carbide and silicon nitride, so they are discussed in the chapter on **High Temperature Corrosion of Ceramics and Refractory Materials**. Thus, the focus of this chapter is on the high temperature corrosion behavior of aluminide intermetallic alloys.

### 1.25.1.1 General Uses of Intermetallic Alloys

The low density of intermetallic aluminides is primarily due to their high aluminum content, which also promotes the formation of an aluminum scale for good high temperature corrosion resistance. Intermetallic compounds also have good high temperature strength and creep resistance, but the mechanical properties at low temperatures (including ambient room temperature) are inferior to those of metal alloys. In particular, intermetallic compounds tend to have low ductility

because of the difficulty of slip in their ordered structures, which leads to low fracture toughness and creates challenges in the fabrication of intermetallic alloys and their implementation in engineering structures. The synthesis of intermetallic alloys is complicated because of the larger differences in melting temperature among the constituent elements, which limits the available fabrication processes. In addition, the properties of intermetallic alloys depend strongly on small changes in composition, so compositional control during synthesis and processing is particularly important.

Despite these significant engineering challenges, the attractive high temperature properties of intermetallic alloys have led to their use in a variety of high temperature applications.<sup>1–3</sup> One of the most promising applications of intermetallic alloys is for components in aeroturbine engines, where increases in operating temperature and decreases in weight improve engine efficiency and performance. Although low density is particularly important in aerospace applications, intermetallic alloys have also been used in other applications, such as valves and turbocharger rotors in high-performance internal combustion engines for automotive applications.

### 1.25.1.2 Common Intermetallic Alloys

Many of the promising intermetallic aluminide alloys have been developed from the nickel- and iron-based high temperature alloys described in the chapter on **High Temperature Corrosion of Alumina-forming Iron, Nickel and Cobalt-base Alloys**. Intermetallic alloys have also been developed in the titanium–aluminum system. In all cases, the intermetallic compounds form ordered crystal structures, some examples of which are shown in **Figure 1**. Plastic deformation by dislocation movement in such ordered structures is more difficult than in disordered metallic structures, so these compounds have high strength and low ductility. Some of the characteristics of these widely used systems are described in the following sections.

#### 1.25.1.2.1 Nickel aluminides

Alloys based on both  $\text{NiAl}$  and  $\text{Ni}_3\text{Al}$  have been developed. As shown in **Figure 2**,  $\text{NiAl}$ , which forms the cubic B2 structure (**Figure 1(a)**), has a much wider range of stoichiometry than  $\text{Ni}_3\text{Al}$ , which forms the cubic  $\text{L}_{12}$  structure (**Figure 1(c)**).  $\text{Ni}_3\text{Al}$ -based alloys exhibit an anomalous temperature dependence of flow stress, in which the strength

**Figure 1** Crystal structures of selected intermetallic compounds in the Ni–Al, Fe–Al, and Ti–Al systems. (a) B2 (NiAl, FeAl), Pearson symbol *cP2*, structure type CsCl, space group *Pm* $\bar{3}$ *m*. (b) *L1*<sub>0</sub> (TiAl), Pearson symbol *tP4*,

increases with increasing temperature up to about 700 °C and then decreases at higher temperatures. Polycrystalline Ni<sub>3</sub>Al is difficult to fabricate because of its low deformability. Although their ductility can be improved with boron, Ni<sub>3</sub>Al-based alloys have relatively large densities and do not offer significant advantages over nickel-based superalloys. NiAl-based alloys, however, have a higher aluminum content, which decreases density and also improves oxidation resistance. NiAl-based alloys have a higher melting temperature and better creep resistance compared to nickel-based superalloys. The strength can be improved with the addition of niobium or tantalum, which leads to the formation of Laves phases, and the ductility can be improved with alloying additions such as chromium, molybdenum, rhenium, and iron. However, the creep resistance of NiAl above 1000 °C is not good.

#### 1.25.1.2.2 Iron aluminides

The iron–aluminum system is similar to the nickel–aluminum system, in that both Fe<sub>3</sub>Al and FeAl compounds are formed. Like NiAl, FeAl forms the cubic B2 structure (Figure 1(a)), but Fe<sub>3</sub>Al forms the D0<sub>3</sub> structure (Figure 1(d)). The tendency towards ordering in the iron–aluminum system is not as strong as that in the nickel–aluminum system, as indicated by the large disordered ferrite region shown in the phase diagram in Figure 3. As in the nickel–aluminum system, the strengths of Fe<sub>3</sub>Al-based alloys increase with increasing temperature to about 500 °C and then decrease at higher temperatures. However, FeAl offers more advantages over superalloys than NiAl. In particular, the fracture toughness and specific properties of FeAl-based alloys are better than those of NiAl-based alloys, but ductility is low compared to metal alloys. The ductility can be improved with alloying additions such as zirconium. Another difference between the iron–aluminum and nickel–aluminum systems is that carbon is often used in the iron–aluminum system to improve strength through carbide strengthening.

### 1.25.1.2.3 Titanium aluminides

Titanium aluminide alloys have the lowest densities among the three common aluminide systems and thus offer the best specific properties. The phase diagram in [Figure 4](#) shows that Ti<sub>3</sub>Al and TiAl have similar ranges of stoichiometry. TiAl forms the tetragonal L1<sub>0</sub> structure ([Figure 1\(b\)](#)), while Ti<sub>3</sub>Al forms the hexagonal D0<sub>19</sub> structure ([Figure 1\(e\)](#)). Both Ti<sub>3</sub>Al- and TiAl-based alloys have been developed, but the best ductility is achieved with two-phase (Ti<sub>3</sub>Al + TiAl) alloys. Production of the desirable two-phase microstructure requires careful control of both the chemical composition and the heat treatment process. The aluminum content in Ti<sub>3</sub>Al is typically not sufficient for good oxidation resistance, so the most promising alloys consist entirely or mostly of the  $\gamma$ -phase (TiAl in the L1<sub>0</sub> structure). The mechanical properties can be improved by adding substitutional elements such as chromium, as well as interstitial elements such as carbon and boron. The

high reactivity of titanium creates challenges in attaining corrosion resistance, as will be discussed later, as well as in reliable alloy production.

## 1.25.2 Oxidation

A major difference between titanium aluminides and the other two common aluminide systems (nickel and iron) is that titanium is much more active than either iron or nickel. This is illustrated in the Ellingham diagram shown in [Figure 5](#). Titanium can change valence from Ti<sup>2+</sup> to Ti<sup>4+</sup>, so there are several titanium oxides, a few of which are included in [Figure 5](#). The two important titanium oxides are TiO, which is in equilibrium with titanium metal, and TiO<sub>2</sub>, which is stable in air. The free energy of TiO (per mole of oxygen) is about the same as that of Al<sub>2</sub>O<sub>3</sub>, indicating there is a strong competition between the formation of titanium and aluminum oxides on TiAl. In comparison,

**Figure 3** FeAl phase diagram. Reproduced from *Binary Alloy Phase Diagrams*, 2nd ed., ASM International, Materials Park OH, 1996, with permission from ASM International.

nickel and iron oxides are much less stable than  $\text{Al}_2\text{O}_3$ , so the amount of aluminum in the alloy required for the formation of an  $\text{Al}_2\text{O}_3$  scale is much less in nickel and iron aluminides than in titanium aluminides. Because of this significant difference in oxide stabilities, nickel and iron aluminides have, in many ways, similar oxidation behavior and will be discussed together in the next section. This will be followed by a section on titanium aluminides, and then a section on some less commonly used aluminide alloys.

### 1.25.2.1 Nickel and Iron Aluminides

There are several general reviews of the oxidation of intermetallic alloys<sup>4-6</sup> as well as reviews that focus on either the nickel-aluminum<sup>7,8</sup> or iron-aluminum<sup>9</sup> system.

#### 1.25.2.1.1 Scale properties/structure

As a result of the large differences in oxide stability (Figure 5),  $\text{Ni}_3\text{Al}$ ,  $\text{NiAl}$ ,  $\text{Fe}_3\text{Al}$ , and  $\text{FeAl}$  are in equilibrium with  $\text{Al}_2\text{O}_3$ , so  $\text{Al}_2\text{O}_3$  is always present

in the scale formed during oxidation. However, nickel and iron oxides can also exist in the scale, either as pure oxides (e.g.,  $\text{NiO}$ ,  $\text{Fe}_2\text{O}_3$ ) or mixed oxides (e.g.,  $\text{NiAl}_2\text{O}_4$  spinel). In addition, with long-time exposure, the growth of an  $\text{Al}_2\text{O}_3$  scale depletes the alloy of aluminum, so the amount of aluminum required to maintain a protective scale is higher than the minimum for thermodynamic stability or initial alumina formation. Pettit<sup>10</sup> characterized the oxidation behavior of nickel-aluminum alloys and found that  $\text{Ni}_3\text{Al}$  alloys form a scale with alumina and  $\text{NiO}$  or the  $\text{NiAl}_2\text{O}_4$  spinel, whereas  $\text{NiAl}$  alloys form a protective alumina scale. Once the critical aluminum content for a protective alumina scale is reached, additional aluminum has little effect on the oxidation rate for short-term exposures. However, with longer exposures, the aluminum content of the alloy beneath the scale can decrease, which leads to an increase in the oxidation rate. Changes in the aluminum content can also affect the microstructure. For example, the decrease in the aluminum content in  $\text{FeAl}$  can lead to a disordered structure (i.e.,  $\text{FeAl}$

**Figure 4** TiAl phase diagram. Reproduced from *Binary Alloy Phase Diagrams*, 2nd ed., ASM International, Materials Park OH, 1996, with permission from ASM International.

to  $\alpha$ -Fe in **Figure 3**) below the oxide scale. Such changes can affect the oxidation behavior, as diffusion rates in the alloy will determine the magnitude of any changes in alloy composition at the alloy–scale interface, which determines the oxide phases formed in the scale.

In addition to alloy composition, microstructure also affects the oxidation behavior. For example, a finer alloy grain size can lead to reduced oxidation rates, because the diffusion of aluminum to replenish the aluminum used to form the alumina scale can reach the scale faster by grain boundary diffusion. A fine-grained microstructure has also been shown to improve the adherence of an alumina scale on NiAl.<sup>11</sup> Scale adherence is particularly important during thermal cycling, as thermal stresses are generated in the scale due to differences between the coefficients of thermal expansion of the scale and the alloy. However, stresses can be generated in the scale even in isothermal oxidation due to growth or transformation stresses in the oxides. In addition, porosity or

segregation of particular elements to the alloy–scale interface can lead to weakening of the interface.

Porosity is often formed beneath the scale formed on nickel and iron aluminide alloys. The formation of porosity is generally attributed to the coalescence of vacancies formed during the growth of alumina. **Figure 6** shows the transport processes that occur during the growth of an alumina scale on an aluminide alloy. Bulk alumina grows by the outward diffusion of aluminum through the inward diffusion of aluminum vacancies, which are created at the oxide surface from oxygen in the gas phase. The vacancies are filled by aluminum from the existing oxide, so that the new oxide is formed on the outer surface. The aluminum vacancies migrate to the alloy and are filled with aluminum from the alloy, which creates vacancies in the alloy. Once the concentration of these vacancies exceeds the maximum concentration in the alloy, pores will form.

The growth process at grain boundaries is generally attributed to the inward migration of oxygen rather than to the outward migration of aluminum.

**Figure 5** Ellingham diagram for nickel, iron, titanium, and aluminum oxides. Data from Kubaschewski, O., Alcock, C. B. *Metallurgical Thermochemistry*, 5th ed., Pergamon Press, 1979; Chase M.W., Jr. (Ed.), NIST-JANAF Thermochemical Tables, 4th ed., J. Phys. Chem. Ref. Data, Monograph No. 9, 1998.

**Figure 6** Transport during growth of alumina scale on nickel aluminide alloys. The predominant inward diffusing oxygen species has not been determined, so oxygen interstitials are used as an example.

Although the specific oxygen defect by which oxygen is transported is not well established, for illustrative purposes, oxygen interstitials are shown in **Figure 6**. Regardless of the specific predominant oxygen defect, however, inward migration of oxygen will lead to the forming of new oxide at the alloy–scale interface. Inward-growing scales generally contain less porosity at the alloy–scale interface as compared to outward-growing scales. However, in the Ni–Al system, porosity can still form within the inward-growing scale. The formation of porosity is generally attributed to

the Kirkendall effect, as, for nickel-rich compositions, the diffusion constant for aluminum in NiAl is smaller than that for nickel in NiAl.<sup>12</sup> Thus, the diffusion of nickel away from the scale into the alloy is faster than the diffusion of aluminum from the bulk toward the scale, which leads to a net movement of mass away from the scale and the formation of vacancies in the metal beneath the scale. The concentration of vacancies continues to increase with increasing oxidation and eventually leads to the formation of pores. The Kirkendall effect can occur regardless of where

the new oxide forms. However, the Kirkendall effect does not occur for aluminum-rich compositions of NiAl, because, in this case, the diffusion of aluminum is not slower than that of nickel. This mechanism is supported by the observation that the number of voids formed decreases with decreasing grain size, as the larger amount of grain boundary diffusion in the finer grained material would reduce the amount of vacancies formed.<sup>13</sup>

The most important effect of the formation of porosity at the alloy–scale interface is that it weakens scale adhesion. The voids can act as stress concentrators and detachment of the oxide has been observed at the pores.<sup>14</sup> Pore formation does not, however, appear to significantly affect the oxidation rate. Although the loss of contact between the alloy and the scale at pores or voids might be expected to affect the scale growth, the  $\text{AlO}_x$  vapor pressure is large enough for vapor-phase transport of aluminum across the void to occur. The number and size of voids increase with oxidation time and the growth of voids in directions parallel to the surface is faster than that perpendicular to the surface.<sup>15</sup> Void formation has been attributed to the growth of the oxide around perturbations at the alloy–scale interface.<sup>16</sup>

Corundum ( $\alpha\text{-Al}_2\text{O}_3$ ) is the most stable form of alumina and the scale formed on nickel- and iron aluminide alloys is predominantly  $\alpha\text{-Al}_2\text{O}_3$ . However, the first alumina phase to form is generally one of the metastable alumina phases – usually  $\theta$  or  $\gamma$ , but occasionally  $\delta$ . These transient phases form on nickel and iron aluminide alloys, but are especially prevalent on NiAl. The crystallographic orientation of the  $\theta$ - or  $\gamma\text{-Al}_2\text{O}_3$  phases is typically aligned with that of the alloy, and the oxides can grow epitaxially, as observed by transmission electron microscopy<sup>17</sup> and low energy electron diffraction.<sup>18</sup> Epitaxial growth is maintained for a longer time on NiAl crystals with the (001) and (012) orientations as compared to those with (011) and (111) orientations.<sup>19</sup> The transient phases grow by outward diffusion of aluminum, but at a higher growth rate (with lower activation energy) as compared with  $\alpha\text{-Al}_2\text{O}_3$ .<sup>20,21</sup> The transport of aluminum in  $\theta\text{-Al}_2\text{O}_3$  is sufficiently high for the overall growth rate of the scale to be controlled in some cases by diffusion of aluminum from the bulk of the alloy to the alloy–scale interface, rather than the diffusion of aluminum through the scale to the surface.<sup>22</sup> As expected for meta-stable phases, the transient alumina phases are more prevalent at lower temperatures.<sup>23</sup> They are also more prevalent at low oxygen partial pressures and high

humidity. The transient alumina phases eventually transform to the more stable  $\alpha\text{-Al}_2\text{O}_3$  phase, which leads to a reduction in the oxidation rate, but volumetric changes associated with the phase transformation can generate stresses that can affect the morphology of the oxide scale.

The stresses generated in the  $\alpha\text{-Al}_2\text{O}_3$  are tensile, but relax with time.<sup>24</sup> Relaxation can occur by deformation in either the alloy or the oxide, and thus depends on the microstructure. Fine grains in either phase will enhance this deformation (i.e., creep of the oxide or grain-boundary sliding in the alloy), and thus accelerate relaxation of the stresses. The stresses can also lead to convolution of the alloy–scale interface, which is commonly referred to as rumpling.<sup>25</sup> Although the interface of the rumpled scale is irregular, contact is maintained between the alloy and the scale. The rumpling is associated with swelling of the scale, which is attributed to the different diffusion rates of nickel and aluminum in NiAl (i.e., the same Kirkendall effect that leads to void formation beneath the scale).<sup>26</sup> This has led to the suggestion that rumpling is initiated by swelling of individual grains in the alloy.

The  $\alpha\text{-Al}_2\text{O}_3$  forming from the transient oxides has been reported to nucleate at both the scale–gas interface<sup>27</sup> and at the alloy–scale interface.<sup>28</sup> After nucleation, the transformation progresses in directions both perpendicular to the surface (inward or outward) and parallel to the alloy surface (lateral) and can lead to the formation of ridges as illustrated in **Figure 7**.<sup>6</sup> The lateral growth of  $\alpha\text{-Al}_2\text{O}_3$  from the nucleation site results in low-angle grain boundaries, which are oriented radially from the nucleation site. The transformation of the transient alumina phase creates tensile stresses in the  $\alpha\text{-Al}_2\text{O}_3$  that can lead to the formation of radial cracks with associated accelerated growth, which can result in ‘spokes’ along the radial cracks (not shown in **Figure 7**). The outer ridges form because the transient phases in this region are the last to transform to  $\alpha\text{-Al}_2\text{O}_3$  and the higher growth rate of the transient oxides leads to a thicker scale in the region. The ridges do eventually transform to  $\alpha\text{-Al}_2\text{O}_3$  and high-angle grain boundaries are formed in the ridges at the boundaries between  $\alpha\text{-Al}_2\text{O}_3$  grown from adjacent nuclei. The high angle boundaries allow for more short-circuit migration of oxygen (as shown in **Figure 6**), so the growth rate of the ridges can continue to be higher than that inside the ridge, where only low-angle boundaries are present. The transformation stresses are relaxed with time and the scale eventually consists of columnar  $\alpha\text{-Al}_2\text{O}_3$  grains.

**Figure 7** Ridge formation in alumina scale formed on nickel aluminide alloys.<sup>6</sup>

In iron aluminides, the nucleation of  $\alpha\text{-Al}_2\text{O}_3$  can be enhanced by  $\text{Fe}_2\text{O}_3$ , which can be present in the oxide scale and act as a template or nucleation site for the  $\alpha\text{-Al}_2\text{O}_3$ . This transformation of the transient oxides to  $\alpha\text{-Al}_2\text{O}_3$  enhances rumpling or wrinkling of the scale. The degree of wrinkling increases with increasing temperature and aluminum content and also depends on the crystallographic structure (ordered or disordered) and orientation. Another difference between iron- and nickel aluminide alloys is that the  $\text{Fe}_2\text{O}_3$  formed on iron aluminides is often mixed with the alumina, whereas the  $\text{NiO}$  or spinel formed on nickel aluminides is usually located on the outer scale surface.

#### 1.25.2.1.2 Effect of atmospheres/impurities

In systems in which the active component provides the oxide for good corrosion resistance, such as nickel and iron aluminides, a reduced oxygen partial pressure is typically beneficial to the corrosion resistance, because it promotes the formation of the protective scale. If the oxygen pressure is sufficiently low, the oxide of the base metal could become unstable. However, even if the oxide of the base metal is stable, the dissolution of oxygen into the alloy is reduced at lower oxygen partial pressures, which reduces the formation of internal oxidation and promotes the formation of an external protective scale. Because the low oxygen partial pressure can promote a protective scale, preoxidation in low oxygen partial pressures is often used to improve the oxidation resistance. These trends apply to the nickel- and iron-aluminum systems as the amount of alumina in the scale is typically larger for oxidation in lower oxygen partial pressures, but there are exceptions. For example, the lower oxygen partial pressure stabilizes the transient oxides,

which, as discussed earlier, leads to higher growth rates. Nickel dissolves more readily in the transient oxides, so the outward diffusion of nickel is more prevalent in low oxygen partial pressures.<sup>29</sup> The dissolution of nickel has been postulated to increase the ionic transport number, but the effect on the parabolic rate constant is not significant.<sup>30</sup> At very low oxygen partial pressures, the formation of nickel oxide can be completely eliminated. Although this would seem to be beneficial, since alumina, rather than  $\text{NiO}$ , provides the good oxidation resistance, the absence of  $\text{NiO}$  can lead to higher stresses in the oxide scale.<sup>31</sup>

The presence of water vapor has less effect on the oxidation of alumina-forming alloys compared with its effect on chromia-forming alloys. Although water vapor often does not significantly affect the oxidation rate of aluminides, it can lead to increased spallation and oxidation rates for  $\text{NiAl}$ .<sup>32,33</sup> The increased spallation has been attributed to the hydration of the alumina scale. Hydrate phases are not stable at oxidation temperatures, but they can form during cooling and generate stresses in the scale, which promote scale spallation.<sup>32</sup> Although water vapor generally has little effect on the oxidation rate of iron aluminides, increased rates have been observed in some experiments.<sup>34</sup> Such variable results suggest that water vapor may influence transient phase transformations, which can be affected by minor changes in scale microstructure or morphology.

The most important impurity for the oxidation of alumina-forming oxides is sulfur, which can increase porosity at the alloy-scale interface and enhance crack propagation.<sup>35,36</sup> Sulfur diffuses to the scale and initially adsorbs to the surface of pores. Once a continuous alumina scale is formed, the sulfur segregation

expands to the alloy–scale interface. As increased porosity and sulfur segregation weaken the scale adherence, sulfur is detrimental to oxidation resistance. The diffusion rate of sulfur in NiAl decreases with increasing aluminum content; therefore the amount of segregation, and thus the associated detrimental effects, are greater for lower aluminum contents. In iron aluminides, sulfur initially adsorbs to the pore surface and subsequently cosegregates with aluminum. The presence of sulfur increases the scale convolution, which, as discussed earlier, results from growth and transformation stresses.

#### 1.25.2.1.3 Effect of alloying additions

The oxidation resistance of aluminide alloys can be improved with alloying additions. Reactive elements have been shown to be beneficial to the oxidation of aluminide alloys by reducing the amount of porosity that forms at the alloy–scale interface.<sup>37,38</sup> One of the mechanisms proposed for this beneficial effect of reactive elements is that the reactive elements segregate to the grain boundaries in the oxide scale and form oxides that block the outward diffusion of cations.<sup>36,38,39</sup> Decreasing the outward diffusion of cations leads to an increase in the proportion of growth by inward diffusion of oxygen, which, as discussed earlier, reduces the amount of porosity formed at the alloy–scale interface and thus improves scale adherence. This mechanism appears to be more prevalent in nickel aluminides compared to iron aluminides.

The reactive element most commonly added to aluminide alloys is yttrium, which can be added as a metallic alloy or as an oxide in oxide dispersion strengthened (ODS) alloys. In nickel aluminide alloys, the addition of yttrium can lead to the formation of a  $\text{NiY}_x$  phase, which promotes spinel formation and thus is detrimental to oxidation behavior. The formation of  $\text{NiY}_x$  is more likely when yttrium is added as a metallic alloy than when added as an oxide phase.<sup>40</sup> As too large an addition of yttrium can increase stresses in the oxide,<sup>41</sup> yttrium is most effective when added in small amounts as an oxide phase. At low temperatures, yttrium additions promote  $\alpha\text{-Al}_2\text{O}_3$  formation and thus decrease the oxidation rate. However, at high temperatures, where  $\alpha\text{-Al}_2\text{O}_3$  forms easily with or without yttrium additions, yttrium is detrimental by decreasing the grain size of the oxide scale, which increases the amount of short-circuit grain-boundary diffusion and thus increases the oxidation rate.<sup>42</sup>

Another common reactive element used with aluminide alloys is hafnium, which improves the adhesion of the oxide scale.<sup>43</sup> The improvement is

observed at temperatures lower than those at which the general reactive element effects are observed, and is attributed to the formation of hafnium oxides that protrude into the scale and provide anchors, which improve adhesion.<sup>44</sup> Hafnium also improves the plasticity of the scale, which increases the magnitude of stresses that can be accommodated without spallation. The addition of hafnium can significantly extend the lifetime of aluminide alloys, particularly when exposed to cyclic oxidation.<sup>45</sup>

Zirconium is also a commonly added alloy, and, like yttrium, can lead to the formation of an additional intermetallic compound,  $\text{NiZr}_5$ , which can lead to the formation of  $\text{ZrO}_2$  in the scale; therefore, the amount of zirconium added must be limited. Small amounts of zirconium can improve adherence and reduce oxide scale growth rate by increasing grain size. However, zirconium can also be detrimental by impeding the formation of  $\alpha\text{-Al}_2\text{O}_3$  and promoting outward scale growth, which increases growth rates. Zirconium is a strong carbide former, so if zirconium is added with carbon, which is commonly added to iron aluminides, the ratio of zirconium to carbon must be controlled, so that the appropriate amount of zirconium is available to beneficially affect the oxidation behavior.

Other reactive elements, such as titanium and cerium, have also been shown to decrease the oxidation rate, either by decreasing the outward diffusion of aluminum or by increasing the grain size of the oxide. However, not all reactive elements are beneficial to oxidation behavior; e.g., lanthanum leads to both a higher oxidation rate and lower scale adherence.

Transition metals are often used as alloying additions for aluminide alloys. Chromium is commonly added to intermetallic alloys to improve ductility and minimize environmentally assisted crack embrittlement. Chromium is beneficial to the alumina-forming nickel- and iron-based alloys, because it reduces the amount of aluminum required to avoid internal oxidation and form a protective scale. Chromium has a similar effect in  $\text{Ni}_3\text{Al}$  as it reduces the amount of aluminum required to maintain an effectively rehealing scale for long oxidation exposures. Chromium affects the transformation of  $\theta\text{-Al}_2\text{O}_3$  to  $\alpha\text{-Al}_2\text{O}_3$ , although the reported effects are mixed as chromium has been reported to both inhibit<sup>42</sup> and promote<sup>21</sup>  $\alpha\text{-Al}_2\text{O}_3$  formation. Chromium dissolves in  $\theta\text{-Al}_2\text{O}_3$ , which would explain the inhibitive effect, as the chromium diffusion may be required for  $\alpha\text{-Al}_2\text{O}_3$  formation.<sup>46</sup> At the same time, chromium appears to accelerate

nucleation of  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>. The effects of chromium on the oxidation rate are likewise mixed as it has been reported to both increase and decrease the oxidation rate. Chromium can segregate to the alloy–scale interface and lead to additional phase formation, which decreases adherence and is therefore detrimental to oxidation resistance.

The effects of niobium and tantalum are more consistent than those of chromium. Like chromium, niobium and tantalum are added to improve the mechanical properties. In both cases, a mixed oxide, NiTa<sub>2</sub>O<sub>6</sub> or NiNb<sub>2</sub>O<sub>6</sub>, forms and is detrimental to oxidation resistance. However, if added in small amounts, niobium and tantalum improve the mechanical properties with an acceptably minimal effect on oxidation resistance. Although increasing the niobium content is detrimental to the oxidation resistance, very large niobium contents (i.e., NiAl + NbAl<sub>3</sub> alloys) can lead to the formation of Laves phases, which promote the formation of a protective alumina scale during oxidation.

Refractory metals, such as molybdenum, tungsten, and vanadium, are generally detrimental because of the formation of liquid or gaseous oxides. For example, although molybdenum does not significantly affect short-term oxidation behavior, for longer exposures, the formation of molybdenum oxide vapor phases is detrimental.

Noble metals, such as Pt, Re, and Rh, can be beneficial to the adherence of the oxide scale.<sup>6</sup> For example, the beneficial effect of platinum to the oxidation behavior of NiAl is generally attributed to its interaction with sulfur.<sup>47</sup> Platinum, like sulfur, segregates to the pore surfaces and alloy–scale interfaces. Any platinum present at these locations displaces sulfur, and thus decreases the detrimental effects associated with sulfur segregation. Platinum can also be detrimental by stabilizing  $\theta$ -Al<sub>2</sub>O<sub>3</sub>, which inhibits the formation of  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>, thus increasing the oxidation rate.<sup>23</sup> However, because of the catastrophic effects of scale spallation, the beneficial effects of improved adherence can often outweigh the detrimental effects of increased growth rates. Scale spallation is particularly critical when the aluminide is used as a bond for thermal barrier coatings, which will be discussed in a later section. Large amounts of platinum additions can lead to the formation of a platinum aluminide phase (PtAl<sub>2</sub>), which minimizes depletion of aluminum from the alloy–scale interface. Maintenance of a sufficient aluminum level at the alloy–scale interface prevents the formation of Ni<sub>3</sub>Al, which can lead to local stresses at the

interface, and improves the long-term oxidation resistance of the alloy.

As mentioned earlier, carbon is used to strengthen iron aluminide alloys. Carbon is generally detrimental to oxidation resistance. The oxide scale formed on the carbide phase (Fe<sub>3</sub>AlC<sub>x</sub>) that strengthens the alloy is thicker than, but has the same morphology as, the scale formed on the metal phase. As mentioned earlier, when used with strong carbide formers (e.g., zirconium), the effects of carbide formation must be considered in optimizing the alloy composition.<sup>45</sup> Boron, another interstitial additional alloy, is also generally detrimental to oxidation behavior, but can be beneficial when added with others, such as zirconium or hafnium.

### 1.25.2.2 Titanium Aluminides

The high reactivity of titanium, relative to iron and nickel, creates additional challenges for the formation and maintenance of an alumina scale, because of the competition between aluminum and titanium for oxide formation. However, as mentioned earlier, titanium aluminides have excellent specific properties and so have been developed for aerospace application. There are several reviews of their oxidation behavior.<sup>48–51</sup>

#### 1.25.2.2.1 Scale properties/structure

The minimum aluminum content required for alumina formation on titanium aluminide alloys is much higher than that for alumina formation on nickel or iron aluminide alloys. TiAl is in equilibrium with TiO and Al<sub>2</sub>O<sub>3</sub>, but any lower compositions are not in equilibrium with Al<sub>2</sub>O<sub>3</sub>; so, even before any aluminum depletion occurs, TiAl is at the borderline aluminum composition for Al<sub>2</sub>O<sub>3</sub> formation. Thus, scales formed on titanium aluminides generally contain both aluminum and titanium oxides.

The typical scale morphology of the scale formed on TiAl is shown schematically in Figure 8.

**Figure 8** Schematic of scale formed during oxidation of titanium aluminide alloys.

Although  $\text{TiO}$  is the titanium oxide in equilibrium with the alloy,  $\text{TiO}_2$  is stable in air. While there may be some titanium oxides with valence lower than +4 at the alloy–scale interface, the major portion of the titanium oxide is rutile  $\text{TiO}_2$ . Rutile is an oxygen-deficient oxide, for which the predominant ionic point defects are oxygen vacancies at high oxygen partial pressures and titanium interstitials at low oxygen partial pressures. Platinum marker experiments on the oxidation of pure titanium have shown that the new oxide forms in the middle of the oxide, indicating that the oxygen vacancies are predominant in the outer scale and titanium interstitials are predominant in the inner scale. The oxidation of titanium aluminide is further complicated, as the scale also contains aluminum oxides. As shown in **Figure 8**, the aluminum oxide is often dispersed in the rutile in the inner portion of the scale. The outer portion of the scale is usually  $\text{TiO}_2$ . Sometimes, as shown in **Figure 8**, there is a layer in the middle of the scale where the amount of alumina is higher than that in the inner portion of the scale. These layers could be in part due to the oxygen partial pressure dependence of the ionic point defects in rutile as described earlier. Although the defect chemistry has not been well established, platinum marker experiments have shown that, as in the case of pure titanium, the new oxide forms in the middle of the scale. There is typically an inner layer, which contains nitrogen if the oxidation is performed in air. This inner layer may also contain titanium in a lower valence and/or mixed oxides. The mixed titanium–aluminum oxide phases (X-phase, Z-phase, NCP) are not thermodynamically stable at the oxidation temperature, but can form at the interface and affect the oxidation behavior.

The growth rate of rutile is much higher than that of alumina, so an alumina scale is desired for oxidation resistance. A continuous alumina layer would provide the lowest oxidation rate and has been achieved on some titanium aluminide alloys. However, a mixed scale, as shown in **Figure 8**, is more typical and the growth rate of such a scale is between the rates for alumina and titania growth. Although increasing the amount of alumina is beneficial for oxidation resistance, the morphology is also important. For example, the more continuous the aluminum-rich layer in the middle of the scale (**Figure 8**), the slower is the growth rate. Thus, control of the oxidation rate of titanium aluminum alloys depends critically on the scale morphology. Because of the mixed scale that grows at a rate higher than pure alumina, the oxidation resistances of titanium aluminide alloys are generally

inferior to those of nickel and iron aluminides, so titanium aluminide alloys are usually considered for lower temperature applications.

#### **1.25.2.2.2 Effect of atmosphere and pretreatment**

The presence of a nitrogen-containing layer suggests that nitrogen may influence oxidation behavior. Nitrogen is often considered essentially inert for many oxidation processes. However, titanium, in particular, and aluminum to a lesser extent, are nitride formers, so nitrogen does affect oxidation behavior. The oxidation behavior of titanium aluminide alloys in air is different from that in argon–oxygen mixtures.<sup>49,50</sup> Although the results are somewhat varied, the oxygen rates in air are typically higher than those in oxygen without nitrogen for the same oxygen partial pressure. The detrimental effect of nitrogen is attributed to the nitrogen-containing layer promoting the formation of  $\text{TiO}_2$ . Although the nitride layer contains aluminum and titanium, the amount of titanium is typically higher than that of aluminum. Nitrogen has also been shown to be beneficial to the oxidation behavior of some alloys – particularly alloys with lower aluminum content. The beneficial effect of nitrogen is attributed to nitrogen doping the rutile and decreasing the concentration of the mobile defect, which decreases transport through the scale. Nitrogen may also promote the formation of alumina in the scale by reducing the titanium activity in the alloy.

Because of the delicate balance between alumina and titania formation, small changes can determine which phase nucleates and grows; subtle differences can therefore affect oxidation behavior. For example, surface finish has been shown to significantly affect the oxidation rate in oxygen, but not in air.<sup>52</sup> The surface finish most likely affects nucleation, which implies that the superior performance in oxygen is due to the formation of a phase that is inhibited by either the presence of nitrogen or the surface roughness. Such phenomena are difficult to characterize because they likely depend on transient phases and microstructures, which are not present when the sample characterization is performed after the oxidation experiment is completed.

The alloy microstructure also affects oxidation behavior. For the same alloy composition, the oxidation rate with a lamellar microstructure is lower than that for a duplex microstructure.<sup>53</sup> One of the challenges in the application of titanium aluminide alloys is control of the microstructure, as the microstructure also affects the mechanical properties. Production of

parts with the same microstructure throughout the sample, as well as between samples, is a significant engineering challenge. Microstructural inhomogeneities can lead to locally high corrosion rates or local mechanical weaknesses.

Water vapor in the atmosphere can increase the oxidation rate. This increase is generally attributed to increasing water vapor transport in the scale. Although water vapor does not significantly affect the growth of alumina, it does affect transport in rutile, which is generally the continuous phase in the oxidation scale and thus dominates the overall scale growth rate.

Preoxidation and presulfidation have been used to improve the oxidation resistance of titanium aluminide alloys. There are often conditions in which a protective scale would not form, but could be maintained if it had already formed. Under such conditions, a pretreatment in carefully controlled conditions can be used to form a protective scale, which subsequently grows at a slow rate.

#### 1.25.2.2.3 Effect of alloying additions

The aluminum content in titanium aluminide alloys is more critical than in nickel and iron aluminide alloys. The oxidation resistance of  $Ti_3Al$  is generally poor, and in binary titanium–aluminum alloys, at least 48–50 at% aluminum is generally required for good oxidation resistance. The amount of aluminum required, however, can be reduced with alloying additions.

The alloying addition most widely used for improving the oxidation resistance of titanium aluminide alloys is niobium. During oxidation, the alloy beneath the scale is enriched with niobium, but niobium is also incorporated in the scale. Several explanations for the beneficial effects of niobium additions have been proposed. One explanation is that niobium increases the activity of aluminum in the alloy, but this has not been supported by subsequent thermodynamic measurements of the aluminum activity.<sup>49</sup> Another explanation is that niobium increases the diffusion of aluminum and/or decreases the diffusion of oxygen in the alloy, which reduces the amount of internal oxidation of aluminum and promotes a more continuous alumina scale. The beneficial effect of niobium has also been attributed to niobium doping the rutile scale and decreasing the concentration of oxygen vacancies and/or titanium interstitials. Niobium has also been reported to improve the mechanical integrity of the scale, which improves the resistance to cyclic oxidation. Large amounts of niobium, however, can be detrimental if a  $Nb_2O_5$  phase forms in the oxide scale.

Another common alloying addition for titanium aluminide alloys is chromium, which is added primarily to improve the mechanical properties of the alloy. Small amounts of chromium lead to an increase in the oxidation rate. This increase is typically attributed to the chromium doping the rutile scale and increasing the concentration of oxygen vacancies and/or titanium interstitials. Larger amounts of chromium, however, are beneficial to oxidation resistance. The beneficial effect has been attributed to chromium increasing the aluminum activity in the alloy. While increases in the aluminum activity have been measured, the magnitude of the increase is not sufficient to explain the observed improvements. Another explanation is related to the formation of Laves phases, which form in alloys with high chromium content. The Laves phases have low oxygen solubility and lower titanium activity, both of which promote a more protective alumina scale.

Niobium and chromium are sometimes added together and, fortunately, the oxidation behavior appears to be dominated by niobium rather than by chromium. The oxidation rates of alloys with a combination of niobium and other alloying additions such as manganese, zirconia, and hafnium are also similar to those of alloys with niobium as the only alloying addition.

Like chromium, other transition metals, such as iron, nickel, manganese, and vanadium, are generally detrimental to the oxidation of titanium aluminide alloys, while refractory metals, such as tungsten and molybdenum, are beneficial. The beneficial effects of tungsten, like those of niobium, are attributed to decreasing the oxygen solubility in the alloy (to inhibit internal oxidation) and doping of the rutile (to reduce oxygen vacancies and/or titanium interstitial concentrations).

Silicon additions can be beneficial to the oxidation resistance of titanium aluminide alloys. If silicon is present in the alloy, silica will usually form in the scale. However, silica is often dispersed so that it is not effective for reducing the oxidation rate. In some cases, silicon additions lead to a continuous silica layer, which provides a barrier to oxygen diffusion and thus improves the oxidation resistance. However, this layer leads to stresses during thermal cycling and is thus detrimental to the cyclic oxidation resistance.

Noble metals have mixed effects on the oxidation of titanium aluminide alloys. Platinum and gold are detrimental to oxidation resistance, but silver is beneficial.<sup>54</sup> Silver promotes the formation of  $\theta-Al_2O_3$ , which, as discussed earlier, grows at a faster rate than  $\alpha-Al_2O_3$  and thus would seem to be detrimental. However, the  $\alpha-Al_2O_3$  formed from transient alumina

is continuous and the oxidation rate of the alloy is the same as that for the growth of an alumina scale. The beneficial effect of silver decreases with increasing temperature, presumably because it results from the transient formation of  $\theta$ - $\text{Al}_2\text{O}_3$ , which is metastable and thus becomes less prevalent with increasing temperature. The addition of small amounts (1–3%) of chromium to silver-doped alloys is detrimental to oxidation resistance, but with larger amounts (5–7%) the oxidation rate is reduced to that of an alumina-forming alloy.<sup>55</sup> The excellent oxidation resistance of these alloys, like the high-chromium-content alloys described earlier, is attributed to the presence of Laves phases in the alloy microstructure.

Reactive elements are used as alloying additions in titanium aluminide alloys, but not to the extent, or to the same beneficial effect, as in nickel and iron aluminide. Small amounts of reactive elements, such as zirconium, hafnium, and yttrium, are beneficial to oxidation resistance. Hafnium has been shown to improve scale adherence. Zirconium, while beneficial for short oxidation exposures, eventually leads to the formation of zirconia, the transformation of which creates stresses in the oxide scale.

One of the most successful recent approaches for improving the oxidation resistance of TiAl-based alloys is the addition of halogen elements, such as fluorine, chlorine, or bromine. The addition of the appropriate amount of a halogen element can lead to a continuous alumina scale and kinetics following the growth of an alumina scale. Various explanations have been proposed for the beneficial effect of halogen additions. One explanation is that chlorine doping of the scale decreases the oxygen vacancy and/or titanium interstitial concentration (i.e., the same as that of niobium and tungsten doping).<sup>56</sup> Other explanations are that the formation of  $\text{TiO}_2$  is inhibited by the presence of the halogen element<sup>57</sup> or by a reduction in titanium activity due to volatilization of titanium. The explanation that best illustrates the long-term effect is shown in Figure 9.<sup>58,59</sup> In this model, aluminum is transported from the alloy to the scale–gas interface in a gas phase that diffuses through pores or microcracks in the scale. Once the aluminum-containing vapor reaches the scale surface, it reacts with oxygen to form alumina and evolves chlorine, which can diffuse back to the alloy and form more of the aluminum-containing species. The chlorine that evolves is thus recycled and provides a mechanism for the transport of aluminum to heal pores and/or cracks in the scale. For this mechanism to work, chlorine partial pressure must be in a critical

**Figure 9** Vapor transport mechanism for beneficial effect of halogen additions on the oxidation of titanium aluminide alloys.<sup>58,59</sup>

range: it must be high enough to transport sufficient aluminum to maintain the protective scale, but if it is too high, the partial pressure of a titanium chloride species may exceed that of the aluminum-containing species. When the pressure of the titanium species is too high the alumina forms in a whisker-like morphology, which does not provide adequate protection.

To impart its beneficial effect on oxidation resistance, the halogen element is needed only at the surface, so ion implantation is often used to add halogen elements to titanium aluminide alloys. The same is true for other alloying elements added for improved corrosion resistance, especially those which may have detrimental properties on the mechanical properties of the alloy. Thus, ion implantation is used to alloy titanium aluminide alloys with other metallic elements, as well as nonmetallic elements, such as phosphorous.<sup>60</sup> This technique minimizes the amount of alloying elements used by localizing the addition to the location at which the element is needed. This technique would not be effective for an element that is consumed during oxidation, as there is a limited source, which could become depleted after long exposures. However, in the case of halogen additions, the halogen element appears to be recycled, and ion implantation has been shown to improve oxidation resistance for long periods of time.

### 1.25.2.3 Other Aluminides

Most of the aluminide alloys used are from the nickel–, iron–, or titanium–aluminum system. However, there are a few other systems that have been developed, including aluminides of noble and active metals.

As described earlier, the beneficial effect of platinum additions to NiAl is due, in part, to the formation

of a platinum aluminide phase at the alloy–scale interface. Since platinum does not form a stable solid oxide, the only oxide that can form on a platinum aluminide alloy is alumina. The microstructure of the alumina scale is similar to that formed on NiAl, but the adhesion is better on platinum aluminide alloys.<sup>61</sup> The scale growth occurs predominately through short-circuit grain boundary diffusion, so the grain size of the oxide scale affects the oxidation rate. The adhesion can be further improved with zirconia additions, which segregate to the alloy–scale interface and lead to a convoluted, but strong, interface between the alloy and the scale.<sup>62</sup> A platinum aluminide coating is clearly expensive and thus is used in applications where a small amount of material is required, such as in a bond coat, which will be discussed in a later section.

Other noble metal aluminides include those of ruthenium and iridium. Ruthenium aluminide has better ductility than most aluminide alloys and has good oxidation resistance. The scale morphology suggests that the scale grows by outward diffusion of aluminum, although voids are not formed beneath the scale.<sup>63</sup> Two-phase Ru(Al) + RuAl are particularly attractive because of their good ductility. However, the oxidation resistance decreases as the amount of the metal phase increases, because the high oxygen diffusivity of the metallic phase leads to internal oxidation.<sup>64</sup> The oxidation resistance can be improved with platinum additions, but weight loss still occurs during cyclic oxidation.<sup>65</sup> Iridium aluminide is used because iridium has very low oxygen permeability and thus is an excellent oxygen barrier. The oxidation rates of iridium–aluminum alloys are representative of pure alumina scale growth.<sup>66</sup>

An aluminide alloy system that has been investigated because of its high melting point and low density is niobium aluminide.<sup>6</sup> However, niobium aluminides, even with large aluminum concentrations (e.g., NbAl<sub>3</sub>), form mixed oxide scales rather than alumina scales. In particular, the scales contain AlNbO<sub>4</sub> and Nb<sub>2</sub>O<sub>5</sub> and are thus not protective. Zirconium aluminide has been investigated but has poor oxidation resistance because of the formation of ZrO<sub>2</sub>. ZrO<sub>2</sub> not only has high oxygen permeability, but also undergoes phase transitions, which generate stresses in the oxide scale.

### 1.25.3 Hot Corrosion

The presence of other reactive species, such as sulfur and chlorine, in the environment can accelerate the

corrosion of intermetallic alloys. The corrosion can be enhanced if the additional species is in the gas phase, but corrosion is further accelerated if a condensed molten salt phase is formed.

#### 1.25.3.1 Sulfur-Containing Environments

The sulfidation behavior of intermetallic alloys has recently been reviewed.<sup>67</sup> The effects of sulfur on the corrosion rate depend on the oxygen partial pressure and whether a condensed phase is formed.

##### 1.25.3.1.1 Gaseous

The addition of SO<sub>2</sub> to an oxidizing environment does not significantly affect corrosion behavior. While the scale formed in SO<sub>2</sub> contains oxides and sulfides, scales formed in oxygen with SO<sub>2</sub> contain mostly oxides with little or no sulfides.<sup>68</sup> One notable difference between oxidation with and without sulfur is that silver, which as discussed earlier, is beneficial to the oxidation behavior of TiAl, is detrimental to the corrosion of TiAl in sulfur-containing atmospheres.

The corrosion behavior changes as the oxygen partial pressure is reduced. In H<sub>2</sub>–H<sub>2</sub>S–H<sub>2</sub>O mixtures, the oxygen partial pressure is typically sufficiently high for alumina to form and alumina is present in the outer portion of the scale. However, the inner portion of the scale consists of sulfides, which can be mixed, but usually contain little or no aluminum (e.g., TiS for TiAl<sup>69</sup> or FeS for FeAl<sup>70</sup>). As expected from the low aluminum content in the sulfides, increasing the aluminum content in the alloy increases the amount of alumina in the scale. For the corrosion of TiAl, TiO<sub>2</sub> is also formed in the scale. In addition, the rapid transport of titanium in the inner TiS layer leads to depletion of titanium in the alloy, so phases with higher aluminum content, such as TiAl<sub>2</sub> and TiAl<sub>3</sub>, form beneath the scale. The addition of niobium improves the sulfidation resistance of both FeAl and TiAl. Niobium oxides and sulfides form in the scale and the scale adherence is improved with niobium additions.<sup>71</sup>

With further decrease in the oxygen partial pressure in H<sub>2</sub>–H<sub>2</sub>S environments, the oxides become less stable and the scale consists almost entirely of sulfides. For FeAl alloys, FeS and mixed (Fe,Al)S phases are formed in sulfidizing environments. The predominant phase formed during sulfidation of NiAl is Ni<sub>3</sub>S<sub>2</sub>, which can also contain Al<sub>2</sub>S<sub>3</sub> or NiAl<sub>2</sub>S<sub>4</sub> inclusions. For low H<sub>2</sub>S levels the sulfidation rate is reasonably low, but as the H<sub>2</sub>S content increases a Ni–Ni<sub>3</sub>S<sub>2</sub> eutectic forms and leads to large (~4 orders of magnitude) increases in corrosion

rates. The addition of chromium leads to the formation of  $(\text{Cr},\text{Al})_3\text{S}_4$  and further degrades the sulfidation resistance.<sup>72</sup> Similarly, zirconium additions increase the amount of internal corrosion and increase the sulfidation rate. In general, nickel aluminides have poor sulfidation resistance.

TiAl forms a layered sulfide structure in low oxygen-partial-pressure sulfidizing atmospheres.<sup>73</sup> The scale typically contains  $\text{Ti}_3\text{S}_4$ , TiS, and  $\text{Al}_2\text{S}_3$ . The sulfide scale typically contains more titanium than aluminum, so the alloy beneath the scale is depleted in titanium, and aluminum-rich phases, such as  $\text{TiAl}_2$  and  $\text{TiAl}_3$ , form. Alloying addition affect the specific sulfide phases formed, but in most cases do not significantly affect the overall sulfidation rate. Silver and copper additions, however, increase the amount of sulfidation.

### 1.25.3.1.2 Molten salts

The corrosion behavior changes when sulfur is present in a condensed salt on the alloy surface. An oxide scale that is relatively stable in a gaseous environment may dissolve in the salt and lead to increased corrosion rates.

The reaction between FeAl and  $\text{Na}_2\text{SO}_4$  produces a complex mixture of oxygen- and sulfur-containing compounds (e.g.,  $\text{NaAlO}_2$ ,  $\text{NaAl}(\text{SO}_4)_2$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3$ ). The corrosion of the alloy occurs by dissolution of the oxide in the molten salt and internal sulfidation of the alloy. Corrosion resistance can improve with increasing temperature as the more rapid growth of the alumina results in a more protective scale.<sup>74</sup> Similarly, the addition of dispersed  $\text{Al}_2\text{O}_3$  to the alloy improves the corrosion resistance by stabilizing the  $\text{Al}_2\text{O}_3$  in the scale. Carbon additions have been shown to improve the corrosion resistance of FeAl by forming carbides that inhibit sulfur diffusion into the alloy. Boron additions, however, have mixed effects as they have been shown to be both beneficial and detrimental to hot corrosion resistance.

Aluminization of nickel-based superalloys has been used to improve hot corrosion resistance. The oxide scale formed on nickel aluminide alloys during hot corrosion in molten sulfates contains an outer layer of NiO or  $\text{NiAl}_2\text{O}_4$ . The latter has better hot corrosion resistance because of the lower solubility of the spinel, as compared to NiO, in the molten salt.<sup>75</sup> The resistance to molten sulfate corrosion can be improved with the addition of platinum, palladium, or chromium.

The oxide formed during the corrosion of titanium aluminide alloys in molten sulfates contains  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$  with an inner layer of sulfides as

**Figure 10** Schematic of scale formed during corrosion of Ti-50Al in  $(\text{Na},\text{K})_2\text{SO}_4$  at 900 °C.<sup>76</sup>

shown schematically in Figure 10.<sup>76</sup> As with sulfidation in a gaseous environment, the scale contains more titanium than aluminum, so the alloy beneath the scale is depleted in titanium and a layer of  $\text{TiAl}_3$  is formed. Also, as with other sulfidation and oxidation processes, increasing the amount of aluminum in the alloy increases the amount of alumina in the scale and improves corrosion resistance. Niobium is beneficial to the oxidation resistance as it improves scale adherence.<sup>76</sup> Chromium aids the hot corrosion resistance, and, as will be discussed later, is often added to protect aluminide coatings. Vanadium additions, however, increase the amount of scale spallation and are thus detrimental.

### 1.25.3.2 Chlorine-Containing Environments

Chlorine enhances the corrosion rate of most materials and intermetallic alloys are no exception. Chlorine can be present in the gas phase or in a molten salt – either a chloride or mixed salt.

#### 1.25.3.2.1 Gaseous

The primary effect of chlorine in the gas-phase corrosion of aluminide alloys is the formation of volatile chloride species.<sup>77</sup> In particular, the vapor pressure of  $\text{AlCl}_3$  is relatively high and can lead to loss of aluminum and/or void formation in the scale, both of which are detrimental, as loss of aluminum decreases the amount of alumina in the scale, and void formation degrades scale adherence. The addition of zirconium has been shown to reduce the loss of aluminum and thus improve corrosion resistance. In some cases, the liquid chlorides can form from reaction with the chlorine in the gas and can enhance the corrosion rate.

### 1.25.3.2.2 Molten salts

Molten chlorides can also be formed from salts deposited on the alloy surface. For example, the reaction of titanium aluminides with sodium chloride results in the formation of  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{NaTiO}_2$ . The increase in corrosion rate due to the presence of sodium chloride is generally attributed to vapor phase transport via chloride gas species.<sup>78</sup> As discussed earlier, controlled amounts of chlorine, or other halogens, can improve the oxidation of titanium aluminide alloys, but for this beneficial effect to occur, the chlorine content must be limited so that transport of aluminum, but not titanium, occurs. The chlorine levels present during hot corrosion in  $\text{NaCl}$  are high enough for the transport of both titanium and aluminum from the alloy to the scale surface. Under these conditions, the alumina forms as whiskers, rather than as a protective layer, so the corrosion rate is increased.

Hot corrosion in lithium-containing chloride salts, such as  $\text{LiCl-Li}_2\text{O}$  or  $\text{KCl-Li}_2\text{O}$ , results in the formation of multiple mixed oxides. For  $\text{TiAl}$ , in addition to  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$ ,  $\text{LiAlO}_2$  forms in the outer portion of the scale, while  $\text{Li}_2\text{TiO}_3$  forms in the inner portion of the scale.  $\text{LiAlO}_2$  also forms during corrosion of  $\text{NiAl}$  and  $\text{FeAl}$  in lithium-containing salts, but  $\text{NiAl}$  is more resistant than  $\text{FeAl}$  to chloride attack.<sup>79</sup>

The corrosion of titanium aluminide alloys in mixed sulfide-chloride molten salts is similar to that in chloride salts, although in some cases the corrosion in a molten chloride is faster than that in a mixed salt. The chloride vapor transport mechanism described above is active in the corrosion of  $\text{TiAl}$  in a mixed chloride-sulfide salt. Chromium and silver additions to  $\text{TiAl}$  improve the hot corrosion resistance by improving the adherence of the mixed oxide phase (Z-phase) formed at the alloy-scale interface.<sup>76,80</sup> The morphology of the scale formed on titanium aluminide containing 1–3% silver is shown in Figure 11.<sup>80</sup> Niobium, which, as discussed earlier, is generally beneficial to the corrosion of  $\text{TiAl}$ , can be detrimental when added in large amounts because of sulfide phase formation.

The corrosion of nickel aluminide alloys in mixed sulfide-chloride molten salts is similar to that in sulfide melts, presumably due to the absence of significant partial pressures of nickel chloride gas species to provide vapor phase transport analogous to that which occurs in titanium aluminide alloys. The oxide scale formed on nickel aluminide alloys consists of a layer of  $\text{NiO}$  and  $\text{Al}_2\text{O}_3$  above an inner layer of sulfides. The alloy beneath the scale is depleted in

**Figure 11** Schematic of scale formed during corrosion of  $\text{Ti-48Al-(1-3)Ag}$  in  $\text{Na}_2\text{SO}_4 + \text{NaCl}$  at  $800^\circ\text{C}$ .<sup>80</sup>

aluminum and the scale is generally not protective. Silicon additions increase the amount of alumina, and thus improve the oxidation resistance. Oxide ( $\text{Y}_2\text{O}_3$ ) dispersions can also improve the corrosion resistance by improving scale adherence.<sup>81</sup>

### 1.25.3.3 Others

Molten carbonates can also lead to enhanced corrosion of aluminide alloys. Corrosion in lithium-containing carbonates is similar to that in other lithium-containing salts in that  $\text{LiAlO}_2$  is present in the corrosion scale. Because of their high aluminum content,  $\text{NiAl}$  and  $\text{FeAl}$  are used as replacements or coatings on stainless steels and superalloys in molten carbonate environments.

As mentioned earlier, vanadium is detrimental to the corrosion of  $\text{TiAl}$  in sulfate salts. Vanadium is also detrimental when present in a corrosive salt. Vanadium-containing salts are more corrosive than sodium chloride to iron aluminides. The scale formed in  $\text{V}_2\text{O}_5$ -containing salts consists of several mixed oxides and can be quite complex. For example, the weight loss of  $\text{FeAl}$  in a  $\text{V}_2\text{O}_5\text{-Na}_2\text{SO}_4$  mixture increases with increasing temperature up to about  $700^\circ\text{C}$  and then decreases at higher temperatures due to the formation of a more protective scale. The addition of  $\text{Al}_2\text{O}_3$  to the alloy provides some improvement in scale adherence.<sup>82</sup>

## 1.25.4 Coatings

Aluminide alloys are attractive as oxidation resistant coatings, because ductility, while desirable, is less critical in a coating than it is in a structural load-bearing member. Aluminide coatings can be used as coatings for other aluminide alloys with inferior oxidation resistance, but superior mechanical properties.

In addition, aluminide coatings can be applied to metallic alloys that have high ductility, but contain little or no aluminum and thus may have poor oxidation resistance. Coatings can be applied by a variety of techniques, some of which will be discussed in the chapter on **High Temperature Coatings: Protection and Breakdown**. However, diffusion coatings are widely used for aluminide intermetallic alloys and will be discussed in this chapter. Aluminum is typically supplied in a gaseous or liquid phase, but solid-state diffusion is required for the growth of the coating. For aluminide coatings of the same base alloy (e.g., NiAl on nickel-based alloys), only aluminum need be added to form an aluminide phase, although other elements are often added for improved properties. However, for aluminide coatings with a different base than the substrate (e.g., NiAl on steel), both elements of the aluminide phase (e.g., nickel and aluminum for NiAl on steel), must be provided, which complicates the coating process.

#### 1.25.4.1 Aluminide Coatings with Same Base as Substrate

Increasing the aluminum concentration at the surface is especially useful in the titanium–aluminum system, since, as discussed earlier, TiAl is a borderline alumina-former. The formation of TiAl<sub>3</sub> coatings on TiAl-based alloys can improve oxidation resistance.<sup>83</sup> A similar approach can be used in the nickel or iron systems, but an increase in the aluminum content of NiAl- or FeAl-based alloys is less critical, because, with the lower stability of the nickel- and iron-oxide phases, the alumina phase is more stable and the additional aluminum content only provides significant benefit for long exposure times when aluminum depletion occurs. However, aluminide coatings can significantly improve the oxidation resistance of metallic alloys with little or no aluminum. For example, aluminide coatings have been used for more than 30 years to improve the oxidation resistance of superalloys.<sup>84</sup> Such alloys contain several alloying additions, the concentrations of which can change during the diffusion process, and can lead to undesired microstructural changes, such as the formation of topographically close packed (TCP) phases.<sup>85</sup> Similarly, the corrosion resistance of steel can be improved by aluminization to form an iron aluminide coating. In this case, the presence of carbon, which can lead to undesired carbide precipitation, places restrictions on the coating process.<sup>86</sup> In the following sections, the application of aluminide coating processes to simple

and complicated alloy systems will be discussed. While alloying additions from the substrate alloy can complicate the coating process, the coating process can also be used to introduce desired alloying additions for improved coating performance.

##### 1.25.4.1.1 Simple aluminide coatings

The aluminum for growth of the aluminide coating can be introduced through several different methods. One method is to sputter an aluminum, or aluminum-containing, layer on the surface of the alloy. The sputtering process is typically followed by a high temperature anneal for diffusion of the aluminum into the alloy. Another method is to place the substrate in molten aluminum, which provides good contact with the alloy as well as protection from oxidation. The most common method for producing aluminide coatings, however, is pack cementation.

The pack in the pack cementation process consists of 10–30% of an aluminum source (aluminum metal or aluminum-containing alloy) and a few percent of an activator (typically a halide species), which are dispersed in an inert filler (typically alumina). Upon heating, aluminum halide gaseous species are formed and transport aluminum to the substrate material. Pure aluminum can be used as the aluminum source for process temperatures below the melting point of aluminum, while aluminum-containing alloys must be used for higher temperature deposition. Pack cementation processes are referred to as high activity or low activity, based on the aluminum activity in the aluminum source. Coatings formed in a high-activity process are inward-growing as aluminum diffuses into the alloy. Low-activity processes (e.g., Al/Ni < 1), however, result in the outward growth as both elements (e.g., Ni and Al) are deposited. The low-activity process is commonly referred to as chemical vapor deposition (CVD), as both, or all, components of the coating are deposited. One of the advantages of a low-activity process is that impurity elements, such as sulfur and phosphorus, are removed during the process, so that high-quality coatings are produced. The low-activity CVD process is more complicated, but provides flexibility to deposit a variety of coatings.<sup>87</sup>

##### 1.25.4.1.2 Alloyed aluminide coatings

As with bulk materials, the corrosion resistance of aluminide coatings can be improved with alloying additions, so the coating processes are often modified to incorporate other elements in the coating. One example is the introduction of chromium to improve

the resistance to corrosion in chlorine-containing environments. Chromium, as well as reactive element additions, can be deposited simultaneously with aluminum in a pack cementation process by using an alloy containing the desired elements as the source.<sup>88</sup> This process is complicated when steel is used as the substrate, because carbon in the steel reacts with chromium to form chromium carbides. For low carbon contents, the carbide particles form separate precipitates, but for higher carbon contents, even as low as 0.2%, a chromium carbide layer forms and disrupts the coating process. This problem can be overcome by using a two-step process, which is illustrated in [Figure 12](#).<sup>89</sup> In the first step, the pack is heated to a relatively low temperature where there is a significant partial pressure of the aluminum chloride vapor species, but the vapor species of the chromium chloride species is low, so that aluminum, but not chromium, is deposited. Aluminum stabilizes the ferrite structure, so dissolution of aluminum causes a phase change in the iron from austenite to ferrite. Because of the low carbon solubility of ferrite, carbon is rejected into the austenite layer below the ferrite. In the second step, the pack is heated to a higher temperature where the partial pressure of the chromium vapor species increases, so chromium is now deposited and diffuses in the ferrite. Because of the low concentration of carbon in the ferrite, chromium carbides do not form and a high-quality coating is produced. A similar process has been used with a nickel-based superalloy to produce a coating with an outer high-chromium layer, which provides good hot corrosion resistance.<sup>90</sup> Chromium, in larger amounts, can also improve the oxidation resistance of titanium aluminide alloys and is often incorporated in titanium aluminide coatings.

Another element that is commonly added to aluminide coatings is silicon. Silicon additions result in the

**Figure 12** Two-step process for codeposition of aluminum and chromium on steel.<sup>89</sup>

formation of silica, which provides excellent oxidation resistance because of its low oxygen permeability and is particularly resistant to acidic melts. Like chromium, silicon can be added in the pack cementation process, and, also like chromium, a two-step process can be used to produce a coating with the desired composition distribution.<sup>91</sup> Although silicon can be introduced through the vapor phase, the eutectic in the aluminum–silicon system provides an opportunity for the introduction of silicon and aluminum through liquid-phase processes. This includes simple dipping processes as well as surface melting processes, such as laser surface melting. Siliconizing is most widely used for titanium aluminide alloys. Although such processes can result in an outer titanium silicide layer, the scale formed during oxidation is similar to that formed on uncoated titanium aluminide alloys. The outer scales consist of titanium and aluminum oxides, but a silica layer is formed in the inner portion of the scale and improves the oxidation resistance.<sup>92</sup>

Aluminide coatings can also be used as the bond coating between superalloys and thermal barrier coatings (TBC). In this application, in addition to the inherent oxidation behavior, the interface between the thermally grown oxide (TGO) on the bond coating and the TBC must be strong, so that the TBC remains attached to the alloy during use (particularly during thermal cycling). Thus, the adherence of the scale is of greater importance than the growth rate, because a thicker TGO is less of a problem than the loss of the TBC. Because of the importance of adherence, one of the common additions to NiAl bond coating is platinum.<sup>93,94</sup> Platinum-containing coatings maintain good scale adherence even with significant amounts of sulfur, which, as discussed earlier, generally degrades scale adherence. Platinum is typically added as a coating prior to aluminization. There are several commercial pack cementation processes for producing platinum-containing coatings, including high-activity inward-growing coating with the substrate in the pack (e.g., Chromalloy RT22), high-activity inward-growing coating with the substrate above the pack (e.g., Howmet SS82A), and low-activity outward-growing coating (e.g., Thermatech MDC150L).<sup>95</sup> The addition of platinum eliminates void formation at the coating–TGO interface, but voids are observed at the alloy–coating interface, as shown schematically in [Figure 13](#).<sup>96</sup> Void formation beneath the scale can lead to spallation of the scale during thermal cycling, which is especially critical if the coating is used as a bond coat, since such spallation will lead to loss of the TBC. Void formation at the coating–scale interface has been

attributed to both the Kirkendall effect and stresses associated with the transformation of  $\beta$ -NiAl to  $\gamma'$ -Ni<sub>3</sub>Al.<sup>97</sup> The void formation at the alloy–coating interface is less critical than that at the coating–scale interface; as both NiAl and Ni<sub>3</sub>Al are more ductile than alumina, crack propagation is less likely.

As mentioned earlier, large amounts of platinum additions can lead to the formation of PtAl<sub>2</sub>, which in addition to improving the supply of aluminum needed to maintain an  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> layer, also limits the transport of transition metal impurities outward from the aluminide coating into the scale. This is particularly important in coatings for superalloys, which contain elements that can degrade the corrosion protection provided by the coating.

Other noble metals used in NiAl bond coatings include rhenium and palladium. Rhenium acts like platinum in that it promotes the formation of an  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> layer and forms a compound that acts as a diffusion barrier. Palladium helps to stabilize the NiAl phase and maintain sufficient aluminum in the scale. Noble metals can also be used with reactive elements. For example, hafnium and platinum have been used together, where, in addition to improving the oxidation resistance, the formation of a Hf–Pt layer provides a diffusion barrier to prevent loss of aluminum and incorporation of transition metals in the coating and scale.

Titanium aluminide alloys can also be used with TBCs. The TBC has relatively good adherence to the alloy, which is attributed to the better match in the coefficients of thermal expansion as compared to nickel-based superalloys. However, a bond coat, such as TiAlCr or TiAl<sub>3</sub>, is needed for long lifetimes.<sup>98</sup>

#### 1.25.4.2 Aluminide Coatings with Different Base as Substrate

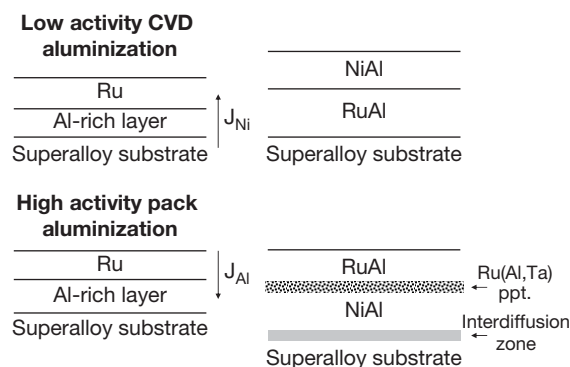

Deposition of an aluminide phase of an element not in the substrate can provide useful properties, but is

**Figure 13** Effect of platinum additions on pore formation in  $\beta$ -nickel aluminide coating after oxidation at 1150 °C.<sup>96</sup>

more complicated than simply increasing the aluminum content of the surface. For example, as discussed earlier, alumina is more stable on NiAl than on TiAl, so NiAl can provide improved long-term corrosion protection, but TiAl is less dense and has better specific strength. Titanium aluminide coated with NiAl combines the advantages of the two materials and can be produced by first electroplating the TiAl with nickel and then aluminizing the nickel layer by pack cementation.<sup>99</sup> The same process can be used for applying a NiAl coating to steel and allows for a reduction in the processing temperature to avoid grain growth or carbide formation in the steel substrate.<sup>100</sup> Similarly, steel, and other non-titanium alloys, can be coated with titanium aluminide by first depositing a layer of titanium and then aluminizing the titanium to form the corrosion resistant titanium aluminide coating.

An analogous process can be used to produce a ruthenium aluminide coating on a nickel-base superalloy.<sup>101</sup> In this case, the coating microstructure depends on whether the ruthenium layer is aluminized using a high-activity pack cementation process or a low-activity CVD process. As shown schematically in **Figure 14**, in a high-activity process, the coating grows by inward diffusion of aluminum, which results in an outer layer of RuAl and an inner layer of NiAl that are separated by a zone containing Ru(Al,Ta) precipitates. In a low-activity process, the coating grows by outward diffusion of aluminum, which results in an outer layer of NiAl. The coating with the outer NiAl layer has superior oxidation resistance. However, the presence of the inner RuAl layer is beneficial as it acts as a diffusion barrier, which can prevent undesired elements from the substrate from entering the outer coating and oxidation scale.

**Figure 14** Ruthenium-modified coatings by low-activity CVD aluminization and high-activity pack aluminization.<sup>101</sup>

### 1.25.5 Summary and Conclusions

Intermetallic aluminide alloys are attractive for high temperature applications. The corrosion resistance of aluminide alloys is achieved by the formation and maintenance of a protective alumina, or alumina-containing, scale. Of the three common aluminide systems, nickel, iron, and titanium, the formation of an alumina scale is most challenging on titanium aluminide alloys because of the thermodynamic stability of titanium oxide. However, titanium aluminide alloys also offer the greatest benefit in terms of improvements in specific properties. In addition to the initial thermodynamic stability of the oxides, long-term corrosion resistance requires maintenance of the protective scale in the presence of stresses (thermal and transformation) and changes in alloy composition with time. In applications where the intermetallic alloys have inadequate mechanical properties for use as structural components, they can be applied as coatings to provide corrosion resistance for structural alloys. Improvements in corrosion resistance can be achieved with alloying additions, but the effects of these elements on other factors, such as mechanical properties, cost, and manufacturability, must also be considered.

environment as the main oxidizing gas species or in addition to larger amounts of 'free oxygen.' From the viewpoint of equilibrium oxygen partial pressure and oxygen/water vapor ratio, the service environments may be divided into four groups:

- A. Wet air or gases originating, for example, from combustion processes with a high oxygen (air) to fuel ratio. In such environments the oxygen content may be as high as 10–20%.<sup>2</sup>
- B. Combustion or exhaust gases originating from combustion processes with low oxygen (air) to fuel ratio. In such gases, which, for example, prevail in car exhaust gas or in the combustion gas of lignite/coal fired power plants, the oxygen content may be as low as 1% or even smaller.<sup>3</sup>
- C. Environments based on steam such as, for example, prevailing in chemical processes or in steam power plants.<sup>4</sup>
- D. Service environments that contain hydrogen in addition to water vapor which may prevail in chemical plants, gasification plants and (solid oxide) fuel cells.<sup>5</sup>

In the first two types of environments (A and B), the equilibrium oxygen partial pressure is hardly affected by the presence of water vapor, whereas in environments C and D it is mainly governed by the absolute water vapor partial pressure or the  $\text{H}_2\text{O}/\text{H}_2$  ratio. The equilibrium oxygen partial pressures in these environments are orders of magnitude smaller than in gases of type A and B. Consequently, oxide phases and vapor pressures of volatile species that form by reaction of metallic components with gases of group A and B may substantially differ from those formed in gases of groups C and D. When comparing the oxidation behavior of metallic materials in dry oxygen with that in water vapor-containing gases, it is therefore important to distinguish between the various types of water vapor-containing atmospheres.

The following sections deal with the oxidation properties of metallic construction materials in gases of type C and D. The main emphasis will be put on describing the oxidation mechanisms in these environments compared to the behavior in dry oxygen, oxygen-inert gas mixtures or air. The examples shown will mainly deal with alloy systems that are commonly used as construction materials in practical applications where typical application temperature ranges for the respective materials are being considered.

**Nomenclature**

In the following sections, the behavior of various materials in  $(\text{Ar}/\text{N}_2-\text{H}_2\text{O})$  and  $(\text{Ar}/\text{N}_2-\text{H}_2-\text{H}_2\text{O})$  is

**1.17.1 Introduction**

In practical applications, metallic construction materials for high temperature components are subjected to a large variety of service environments. Stability and growth rate of the oxide scales that form on the component surfaces during exposure are commonly described on the basis of equilibrium oxygen partial pressures of the various environments. However in many of these applications, water vapor has been found to substantially alter the technologically relevant properties, mainly growth rate and adherence, of the surface oxides.<sup>1</sup> Thereby it has to be considered whether water vapor can be present in the service

compared with that in air, oxygen or various mixtures of oxygen and inert gases. The equilibrium oxygen partial pressures of the two mentioned  $\text{H}_2\text{O}$ -containing gas types at, for example,  $800^\circ\text{C}$  are typically in the range  $10^{-8}$  to  $10^{-18}$  bar. This is obviously orders of magnitude lower than the  $p_{\text{O}_2}$  in the mentioned  $\text{O}_2$ -based gases. Therefore, in the following discussion the mentioned  $\text{H}_2$ -containing gases are frequently termed 'low- $p_{\text{O}_2}$  gases,' and the  $\text{O}_2$ -based environments 'high- $p_{\text{O}_2}$  gases.'

## 1.17.2 Thermodynamic Considerations

### 1.17.2.1 Thermodynamics of the Gas Atmosphere and Stability of Solid Oxides

In mixtures of hydrogen and water vapor, the oxygen partial pressure is substantially lower than in air where  $p_{\text{O}_2}$  is approximately 0.2 bar. The equilibrium oxygen partial pressure can be derived from:

and

$$p_{\text{O}_2} = \left\{ \exp \left( \frac{-\Delta G^\circ}{RT} \right) \right\} / \left( \frac{p_{\text{H}_2}}{p_{\text{H}_2\text{O}}} \right)^2 \quad [2]$$

in which  $\Delta G^\circ$  is the standard free energy of formation.<sup>6</sup>

In pure steam or Ar- $\text{H}_2\text{O}$  mixtures, the equilibrium hydrogen and oxygen partial pressures are

similar, but in the calculations the change in water vapor content due to formation of  $\text{H}_2$ ,  $\text{O}_2$ , and other gas species such as  $\text{HO}_2^{(\text{g})}$  and  $\text{OH}^{(\text{g})}$  has to be taken into account to calculate the oxygen partial pressure of the fully equilibrated gas or gas mixture. The equilibrium oxygen partial pressure in steam and in gases with various  $\text{H}_2/\text{H}_2\text{O}$  ratios in the temperature range  $500$ – $1100^\circ\text{C}$  is presented in **Figure 1**.

**Figure 2** compares the equilibrium oxygen partial pressure of an Ar-50 vol.%  $\text{H}_2\text{O}$  mixture and an Ar- $\text{H}_2\text{O}/\text{H}_2$  mixture ( $\text{H}_2\text{O}/\text{H}_2$  ratio = 1/1) with that of the dissociation pressures of selected oxides. It is apparent that oxides of Cr, Al, Si, and Ti are stable in both atmospheres in the temperature range  $500$ – $1100^\circ\text{C}$ . Fe will easily oxidize in Ar- $\text{H}_2\text{O}$  but only at lower temperatures in the Ar- $\text{H}_2$ - $\text{H}_2\text{O}$  mixture. In the latter gas, Ni and Co will not oxidize.

**Equation [2]** reveals that the equilibrium oxygen partial pressure of an  $\text{H}_2\text{O}/\text{H}_2$  mixture is governed by the  $\text{H}_2\text{O}/\text{H}_2$  ratio and thus independent of the total gas pressure. This is not the case in pure steam or in mixtures of water vapor with an inert gas.<sup>8</sup> In these gases, the equilibrium oxygen partial pressure increases with increasing total pressure (**Figure 3**).

### 1.17.2.2 Volatile Reaction Products in $\text{H}_2\text{O}$ -Containing Gases

The oxidation behavior of metallic materials may be substantially affected by the formation of volatile oxides. Well known examples are  $\text{CrO}_3^{(\text{g})}$ , which

**Figure 1** Equilibrium oxygen partial pressure as function of temperature in various gas atmospheres (calculations carried out with the Program Fact Sage<sup>7</sup>).

**Figure 2** Comparison of the equilibrium oxygen partial pressure of an Ar-50 vol.% H<sub>2</sub>O mixture and an Ar-H<sub>2</sub>O/H<sub>2</sub> mixture (H<sub>2</sub>O/H<sub>2</sub> ratio = 1:1) with that of the dissociation pressures of selected oxides (calculations carried out with the Program Fact Sage<sup>®</sup>).

**Figure 3** Calculated equilibrium oxygen partial pressure in steam at various total pressures. Calculations carried out with the Program Fact Sage [7].

forms in equilibrium with Cr<sub>2</sub>O<sub>3</sub>, and SiO<sup>(g)</sup> in equilibrium with Si or SiO<sub>2</sub>. The vapor pressure of SiO<sup>(g)</sup> increases with decreasing  $p_{O_2}$ , whereas CrO<sub>3</sub><sup>(g)</sup> becomes more significant at high  $p_{O_2}$ . In case of competition between oxide scale growth and volatilization, a simple Tedmon model,<sup>9</sup> in which the overall rate of metal wastage is a function of the parabolic rate constant for oxide growth and the linear rate constant for volatilization, is frequently used to describe the observed kinetics. In the presence of

water vapor, a number of additional volatile species may form. For the three most important protective surface oxides on metallic materials, alumina, chromia, and silica, the following reactions in equilibrium with the respective oxide phases seem to be the most important ones:<sup>10</sup>

Various data sets<sup>11</sup> exist for vapor pressure data of these volatile oxyhydroxides, and in the case of  $\text{CrO}_2(\text{OH})_2$  this literature data substantially differ (Figure 4). More recent data show, for example, for the partial pressure of this oxyhydroxide at 850 °C in Air + 2%  $\text{H}_2\text{O}$ , a variation between  $10^{-8}$  and  $10^{-9}$  bar.<sup>12</sup> On the basis of own experimental data and an extensive evaluation of the various data sources, Opila<sup>11</sup> showed that the rates of evaporation increase in the following order:  $\text{Al}(\text{OH})_3^{(g)} < \text{Si}(\text{OH})_4^{(g)} < \text{CrO}_2(\text{OH})_2^{(g)}$ , as shown in Figure 5. It is apparent from eqn. [3] that the loss of chromium by volatilization

**Figure 4** Temperature dependence of the equilibrium constant  $K$  for the reaction  $1/2\text{Cr}_2\text{O}_3(\text{s}) + \text{H}_2\text{O}^{(g)} + 3/4\text{O}_2^{(g)} = \text{CrO}_2(\text{OH})_2^{(g)}$ . Compiled by Opila<sup>11</sup> using data from various sources.

**Figure 5** Partial pressures of primary volatile species calculated for each oxide at 1 atm total pressure: 0.5 atm  $\text{O}_2$ , 0.5 atm  $\text{H}_2\text{O}$ .<sup>10</sup>

of  $\text{CrO}_2(\text{OH})_2^{(g)}$  should have a significant impact only on the oxidation process in gases in which partial pressures of both oxygen and water vapor are high,<sup>13</sup> and it should not be significant for the overall oxidation process in the low- $p_{\text{O}_2}$  gases considered in the present paper. In such gases, in fact  $\text{Cr}(\text{OH})_3^{(g)}$  is the most volatile chromium compound over the entire considered temperature range but the vapor pressure at 700 °C, for example, is only about  $10^{-13}$  atm. Galerie *et al.*,<sup>14</sup> Michalik *et al.*,<sup>15</sup> and Ehlers *et al.*<sup>16</sup> confirmed that at low- $p_{\text{O}_2}$   $\text{CrO}_2(\text{OH})_2$  does not possess sufficient volatility to be considered, for instance, as a possible cause of breakaway oxidation of ferritic steels in water vapor. Young and Pint<sup>17</sup> showed that the volatile Cr oxyhydroxide may become significant in high-pressure steam.

The data of Opila<sup>11</sup> shows that the reaction products of water vapor with chromia and silica have significant volatility at temperatures above about 800 °C, whereas for alumina this is the case only at temperatures in excess of 1400 °C. It is important to note that the vapor pressures of the most important volatile Al- and Si-containing species are independent of  $p_{\text{O}_2}$  (eqns [4] and [6]) and they can therefore be equally important for oxidation processes in  $\text{H}_2\text{O}$  ( $-\text{H}_2$ )-based gas mixtures and, for example, in wet air.

Also, volatilization of other alloying elements has been considered to play a role in the oxidation process in wet environments. For reaction of the ferritic 9% Cr steel P92 in oxygen/water vapor gas mixtures at 650 °C, formation of volatile species was considered by Milewska *et al.*<sup>18</sup> as function of  $p_{\text{O}_2}$  but with a constant water vapor content of 10%. At a low  $p_{\text{O}_2}$  of  $10^{-19}$  atm the most volatile species are  $\text{Fe}(\text{OH})_2^{(g)}$ ,  $\text{MoO}_2(\text{OH})_2^{(g)}$ , and  $\text{WO}_2(\text{OH})_2^{(g)}$ . With increasing  $p_{\text{O}_2}$  up to  $10^{-1}$  atm,  $\text{MoO}_2(\text{OH})_2^{(g)}$  and  $\text{WO}_2(\text{OH})_2^{(g)}$  remain the most volatile compounds but  $\text{CrO}_2(\text{OH})_2^{(g)}$  and  $\text{Mo}_3\text{O}_2^{(g)}$  also show significant volatility. The hydroxide  $\text{Fe}(\text{OH})_2^{(g)}$  as possible active volatile species in the oxidation of 9% Cr steels in presence of water vapor, especially at high total pressure, was also proposed by Thiele *et al.*,<sup>19</sup> Ehlers *et al.*,<sup>16</sup> and Davis and Dinsdale.<sup>8</sup> This was based on an evaluation by Surman and Castle,<sup>20</sup> but the authors indicated that better data was required to confirm its significance for oxidation processes.

### 1.17.2.3 Considerations for Material Testing in Steam Environments

When testing materials in water vapor-containing gases, impurities in the test gas may have an important effect on the equilibrium oxygen partial pressure

that establishes in the gas. If, for example, an inert gas such as Ar is bubbled through water at controlled temperature to establish a certain partial pressure of  $\text{H}_2\text{O}^{(\text{g})}$ , the equilibrium oxygen partial pressure of the gas mixture at temperatures between 500 and 900 °C is in the range  $10^{-9}$  to  $10^{-6}$  bars (Figure 6). Therefore, traces of oxygen as low as, for example, 1 ppm in the Ar carrier gas may, in this temperature range, substantially affect the equilibrium values. This will not be the case in (Ar)- $\text{H}_2$ - $\text{H}_2\text{O}$  mixtures containing a few percent of  $\text{H}_2$ . Hydrogen will at high temperature react with the  $\text{O}_2$  impurity such that the initial content of oxygen in the carrier gas will become insignificant for the overall equilibrium oxygen partial pressure. However, in pure steam or in Ar- $\text{H}_2\text{O}$  mixtures, not only traces of oxygen but also hydrogen in the initial gas mixture can have a substantial effect on the  $p_{\text{O}_2}$  of the equilibrated gas. For example, the presence of 1 ppm  $\text{H}_2$  in an Ar-4%  $\text{H}_2\text{O}$  gas mixture would, in a large temperature range, be sufficient to destabilize haematite, while traces of oxygen would have the opposite effect (Figure 6). It should be mentioned that traces of hydrogen may, for example, be present in the inert carrier gas, but may also originate from the reaction of the water vapor with the metallic material to be tested.<sup>21,22</sup> The latter effect was claimed to be responsible for differences in

oxide scale composition and thickness in the gas flow direction when testing ferritic steel specimens in slow-flowing Ar- $\text{H}_2\text{O}$  (Figure 7).<sup>22</sup> The effect did not occur if the test gas contained substantial amounts of hydrogen in addition to water vapor.<sup>23</sup>

The possible formation of volatile species due to reaction of oxides with water vapor has important implications for materials testing. Owing to its excellent thermal shock resistance, quartz is frequently used as construction material for reaction tubes and/or specimen holders in oxidation test facilities. In environments containing substantial amounts of water vapor, the formation of volatile Si-containing gas species such as, for example,  $\text{Si}(\text{OH})_4^{(\text{g})}$  can, however, substantially affect the oxidation process, as illustrated in Figure 8. In such test gases, reaction tubes and specimen holders should therefore, for instance, be made of alumina, in spite of problems that might occur due to the poorer thermal shock resistance of this material.

A further consequence of the  $\text{Si}(\text{OH})_4^{(\text{g})}$  formation is that materials or coatings that rely on formation of silica-based surface scales may not be suitable for material protection in steam environments. This is especially the case in high-pressure steam because eqn [4] shows that the vapor pressure of  $\text{Si}(\text{OH})_4^{(\text{g})}$  is proportional to  $[p_{\text{H}_2\text{O}}]^2$ .

**Figure 6** Calculated equilibrium oxygen partial pressures in various Ar- $\text{H}_2\text{O}$ (- $\text{H}_2$ ) gas atmospheres compared with the dissociation pressure of  $\text{Fe}_2\text{O}_3$ , showing effect of trace amounts of  $\text{O}_2$  and  $\text{H}_2$ . ### 1.17.3 Growth Mechanisms of Oxide Scales

#### 1.17.3.1 Kinetics of Surface Reactions

Upon long-term oxidation, the growth of oxide scales is frequently governed by solid-state transport processes within the scale. This results in an oxide thickening, which can, according to the classical oxidation theory developed by Wagner,<sup>6</sup> in many cases be described

by an approximate parabolic time dependence. However, especially in the early stages of oxidation, the kinetics of the surface reactions may be the rate-limiting step in the oxidation process.

Michalik *et al.*<sup>24</sup> studied the early stages of oxidation of Cr at  $1000^\circ\text{C}$  in an Ar-1%  $\text{O}_2$ -2%  $\text{H}_2\text{O}$  mixture using  $\text{H}_2^{18}\text{O}$  as tracer (Figure 9). The authors found that the chromia scale formation for up to exposure times of 3 h virtually contained only  $^{18}\text{O}$ , thus showing that in

**Figure 9** SNMS depth profile after oxidation of chromium for 3 h in Ar-1%  $^{16}\text{O}_2$ -2%  $\text{H}_2^{18}\text{O}$  at 1000°C.<sup>24</sup>

this stage of the oxidation process oxygen transfer via  $\text{H}_2\text{O}^{(\text{g})}$  is much faster than that via  $\text{O}_2^{(\text{g})}$ . Also, Jacob *et al.*<sup>25</sup> reported for chromium oxidized in  $^{18}\text{O}_2/\text{H}_2^{16}\text{O}$  mixtures that oxygen derived from water vapor was the major component of the oxide even though the  $p_{\text{H}_2\text{O}}^{(\text{g})}/p_{\text{O}_2}^{(\text{g})}$  ratio was only 0.05 in that case.

In several studies it was found that whisker formation was promoted by the presence of water vapor.<sup>26,27</sup> Whiskers are believed to be formed at dislocations in the oxide<sup>28</sup> and have hollow cores such that rapid surface diffusion within the whisker can take place and their growth is then limited by the availability of oxidant at the whisker tip.<sup>28</sup> It was proposed<sup>26</sup> that the faster growth of whiskers in moist atmospheres is related to the generally faster dissociation of water molecules than for most other oxidant molecules.

Anghel *et al.*<sup>29</sup> studied the adsorption of  $\text{N}_2$ ,  $\text{H}_2$ , CO, and  $\text{H}_2\text{O}$  on oxidized Cr- and Zr-based materials in the temperature range 400–600 °C. When adding water vapor to CO gas, the dissociation rate of CO on Cr decreased, which can be interpreted as being the result of a blocking effect by water. On the basis of the results of these authors, the following ranking for the tendency of adsorption at high temperatures was made:  $\text{N}_2 < \text{H}_2 < \text{CO} < \text{H}_2\text{O}$ . This might explain the results of Michalik *et al.*,<sup>24</sup> who found pure Cr to form subscale nitrides during exposure at 1000 °C in  $\text{N}_2$ - $\text{O}_2$  but not in  $\text{N}_2$ - $\text{H}_2$ - $\text{H}_2\text{O}$ . Zheng and Young<sup>30</sup> found that for pure Cr at 900 °C subscale nitride formation occurred in  $\text{N}_2$ -CO-CO<sub>2</sub> but not in

$\text{N}_2$ - $\text{H}_2$ - $\text{H}_2\text{O}$  atmosphere with the same equilibrium oxygen partial pressure. The authors explained the results in terms of competitive adsorption of the various gas species on oxide surfaces and grain boundaries. Thus, as  $p_{\text{H}_2\text{O}}/p_{\text{O}_2}$  increases, preferential adsorption of  $\text{H}_2\text{O}$  becomes favored. Evidently, nitrogen can enter and penetrate dry  $\text{Cr}_2\text{O}_3$  grain boundaries, but cannot do so when large numbers of water molecules are present. This confirms the ability of  $\text{H}_2\text{O}^{(\text{g})}$  to interact with the interior of chromia scales modifying their transport properties.<sup>30</sup>

Akermark and Hultquist<sup>31</sup> showed that with an Fe-20% Cr-10% Al alloy oxidized at 920 °C, water dissociation rates decreased with decreasing oxidation rates, and they interpreted this as the result of fewer defects in the more mature alumina scale. In general, it appears that dissociation of a gas molecule such as  $\text{H}_2\text{O}^{(\text{g})}$  is favored by defects in the surface, and the stoichiometric oxides such as alumina may therefore be less active than, for example, FeO.

A number of authors have proposed that the relative acidity/basicity of oxides controls the reaction with water vapor,<sup>32</sup> where water vapor will react more strongly with more acidic oxides (Figure 10). The commonly used method of PZC (point of zero charge) or IEP (isoelectric point) is believed to yield a good relative assessment for oxide ranking, while use of chemical shift measurements by X-ray photoelectron spectroscopy (XPS) or heats of adsorption by calorimetry or gas chromatography yield better absolute values.<sup>33</sup>

**Figure 10** Correlation between the oxidation rate of metals by water vapor at 800 °C and the hydration enthalpy of the corresponding cation.<sup>32</sup>

### 1.17.3.2 Effect of Water Vapor and Hydrogen on Lattice Diffusion in Oxide Scales

The possible effects of hydrogen/water vapor incorporation in the transport properties of oxides were considered by several authors. Hydrogen dissolves in the oxide as protons and is bound to oxide ions to form the substitutional hydroxide  $(\text{OH})_{\text{o}}^{\bullet}$ .<sup>34</sup> These defects may equivalently and more simply be described as interstitial protons  $\text{H}_{\text{i}}^{\bullet}$ . Generally it is found that the concentration of  $\text{H}_{\text{i}}^{\bullet}$  increases with increasing  $p_{\text{H}_2\text{O}}$  and decreasing temperature. The dissolution of protons in an oxide can be written as:

or, by considering gas equilibria,

Thus, at sufficiently low  $p_{\text{H}_2\text{O}}$  or  $p_{\text{H}_2}$ , protons are minority defects. The concentrations of native defects are independent of  $p_{\text{H}_2\text{O}}$  or  $p_{\text{H}_2}$  (at constant  $p_{\text{O}_2}$ ), while the concentrations of protons increase with  $p_{\text{H}_2\text{O}}^{1/2}$  or  $p_{\text{H}_2}^{1/2}$ . At higher  $p_{\text{H}_2\text{O}}$  or  $p_{\text{O}_2}$ , protons may become the dominant defect, compensated for by defect electrons, metal vacancies, oxygen interstitials or acceptor dopants. Many investigations focus on the equilibrium between water vapor, oxygen vacancies and protons as being the most likely:

which, in general, is exothermic so that protons are dominant at low temperatures and oxygen vacancies at high temperatures. It is also important to consider the parallel reaction of dissolution from the gas phase:

Thus, different types of hydrogen-containing species may be present simultaneously, that is, molecular water and OH groups, as is frequently found in glasses.<sup>35</sup> In close-packed structures such as alumina and chromia, dissolution of molecular water would be less favored. Transport of 'water' in oxide scales is claimed to occur by a proton 'hopping' process in which protons localized at oxide ions move by transfer from one oxygen to another. Since oxygen is available everywhere, the net effect of proton diffusion is diffusion of water, and since proton diffusion rates are high compared with those of metal or oxygen, diffusion of 'water' is easy. Although the general principles of the effects of protons can be outlined, the uncertainties regarding transport in the oxides scales of interest are such that it is not possible to predict with any certainty the effects of water vapor on lattice transport.

### 1.17.3.3 Molecular Diffusion in Oxide Scales in Wet Gases

Already in earlier studies it was claimed that, depending on the scale type, the oxidation kinetics in  $\text{H}_2\text{O}$ -containing gases at least partially depends on the ingress of water molecules through the oxides scales. For this to happen, 'microchannels' must be present,

or, as in the case of silica, an open network structure allows the transport of large molecular species.

It is important to consider gaseous or volatile species that might be created during oxidation reactions involving water vapor and how these are transported within the scale. A well-accepted process for vapor or gaseous transport is the dissociative mechanism first proposed by Rahmel and Tobolski.<sup>36</sup> This mechanism is applicable only for scales grown by cation transport and involves interaction with void formed by vacancy condensation.<sup>6</sup> If a void contains both hydrogen and water vapor, oxidation of the surface nearest the metal will occur by reaction with water to form new oxide and the gaseous reaction product hydrogen (Figure 11). Adapting this suggestion to  $\text{Cr}_2\text{O}_3$  and using the Kröger–Vink notation, one can write<sup>37</sup>

This process occurs in the forward direction, on the side of the cavity nearest the metal, and in the reverse direction at the outer surface of the cavity. It provides for rapid inward diffusion of oxygen while the void gradually moves outwards from the metal/oxide interface to the oxide/gas interface.

As mentioned in Section 1.17.2.2, Surman and Castle<sup>20</sup> and Ehlers *et al.*<sup>16</sup> have proposed that volatile  $\text{Fe}(\text{OH})_2^{(\text{g})}$  might participate in the scale-formation process in wet gases and might be an important factor for pore generation in an oxide formed on a 9% Cr steel in wet gas. Using available thermodynamic data, however, Ehlers *et al.*<sup>16</sup> calculated that the vapor pressure of  $\text{Fe}(\text{OH})_2^{(\text{g})}$  is too low to sustain the reaction, but pointed out that these data need verification. The process may be of more importance at high steam pressures.<sup>17</sup>

**Figure 11** Schematic illustration showing oxygen transfer across in-scale voids in water vapor-containing gas. (From Ref. 16 based on the Rahmel–Tobolski mechanism<sup>36</sup>).

Void transport by the Rahmel–Tobolski mechanism or generation of volatile  $\text{Fe}(\text{OH})_2^{(\text{g})}$  obviously requires water vapor to exist within the oxide scale. In addition to proton diffusion, the presence of cracks and fissures in the oxide is a possible mechanism to allow water ingress. Ehlers *et al.*<sup>16</sup> have found that scales grown in water vapor mixtures on the 9% Cr steel P91 are more permeable than those grown under dry conditions, which was demonstrated by  $^{16}\text{O}_2/\text{H}_2^{18}\text{O}$  studies (Figure 12). A competitive adsorption between water and oxygen occurred at inner surfaces, with water being preferentially adsorbed if the  $p_{\text{H}_2\text{O}}/p_{\text{O}_2}$  ratio is  $\geq 1$ .

### 1.17.4 Metallic High Temperature Components in Steam and Steam/Hydrogen Environments

#### 1.17.4.1 General Remarks

Nearly all high temperature metallic construction materials rely for their oxidation protection on chromia or alumina scales that form on the component surface during high temperature service. Only in a few cases, silica, mostly found as sublayer beneath chromia base scales, is of importance for metallic materials protection. Pure silica scales are of far more importance for environmental protection of a number of ceramic materials, for example, of the type Si nitride or carbide.

When comparing the behavior of metallic high temperature components in steam and steam/hydrogen gases with that in oxygen or air, the literature data indicate that the service environment may affect the growth of the protective scale (chromia or alumina) as well as that of the less protective oxides of the base elements (Fe, Ni, Co). Therefore, the effect of the environment on the overall material behavior of alloys with high concentrations of protective scale-forming elements (PSEs) chromium and aluminum may differ from that of lower alloyed materials that form oxide scales of the base elements or alloys that can be considered as ‘borderline’ alloys between protective and nonprotective behavior.

Figure 13 shows the qualitative dependence of the oxidation behavior of Fe-, Ni-, and Co-based alloys as a function of the amount of PSEs, as frequently measured when exposing the alloys to oxygen or air.<sup>6</sup> With small additions of PSEs (group I alloys), the total oxygen uptake frequently tends to be slightly higher than in case of pure base metal oxidation because of doping effects and/or occurrence of internal oxidation.<sup>6,38</sup> With a further increase in concentration of PSEs, the

**Figure 12** MCs<sup>+</sup> secondary ion mass spectrometry profile of P91 steel after 30 h oxidation at 650 °C in N<sub>2</sub>-1% <sup>16</sup>O<sub>2</sub>-4% H<sub>2</sub><sup>18</sup>O showing differences in distribution of <sup>18</sup>O and <sup>16</sup>O in the Fe-based oxide scale. Arrow indicates location of gap in outer magnetite layer. Reproduced from Ehlers, J.; Young, D. J.; Smaardijk, E. J.; Tyagi, A. K.; Penkalla, H. J.; Singheiser, L.; Quadackers, W. J. *Corros. Sci.* **2006**, *48*, 3428–3454.

**Figure 13** Schematic illustration showing qualitatively the effect of Cr and/or Al content on the oxidation rates of Ni-, Fe- and Co-based alloys during exposure in air or oxygen. (The oxidation rates of group I and group III alloys are not necessary independent of the concentration of PSEs, as explained, for example, by Birks *et al.*<sup>6</sup>).

oxidation rate decreases as a result of the formation of larger amounts of more protective oxides in the surface scale. Above a critical concentration of the PSEs, the alloy starts forming a slowly growing scale of chromia or alumina. The exact concentration at which this fundamental change in oxidation mechanism occurs depends on numerous parameters such as temperature, time, gas composition, minor alloying additions, and

surface treatment. Alloys with a concentration of the PSE near the steep drop in oxidation rate (group II alloys) can thus be considered as ‘borderline’ alloys between protective and nonprotective scale formation.

The commercially available alloy systems for high temperature applications are mostly materials of group II and III in Figure 13. Therefore, in the following sections the effect of service environment on the behavior of these types of alloy systems will be described. First, chromia scale formation on pure Cr as well as high-Cr Fe- and Ni-based alloys (group III materials) will be discussed. Subsequently, the scale formation on corresponding ‘borderline alloys’ with intermediate Cr contents (group II) will be treated. Owing to its technological importance, special emphasis will be put on steam oxidation behavior of ferritic/martensitic and austenitic steels in the temperature range 550–650 °C. The final sections will deal with alumina-forming alloys and coatings, including the behavior of ‘borderline’ alumina formers.

### Nomenclature

In the following discussion the chromia and alumina scales will be frequently termed as ‘protective scales’ whereas the oxides of the base elements Fe, Ni, and, for example, Ti will be termed ‘nonprotective oxides.’ This expression is strictly speaking not correct because oxides with relatively high growth rates still offer protection of the metal or alloy. The expressions will, however, be used for convenience.

### 1.17.4.2 Oxidation of Chromium and High-Chromium Alloys

#### 1.17.4.2.1 Oxidation of chromium

In earlier studies, Quadakkers *et al.*<sup>39</sup> found the oxide scale on pure chromium in an Ar/H<sub>2</sub>/H<sub>2</sub>O mixture to grow faster than that formed in air. During cyclic oxidation, however, the overall oxidation resistance of the material was far better in Ar/H<sub>2</sub>/H<sub>2</sub>O because of the better adherence of the scales than that of the scales formed in air. The oxide scales formed in the low-*p*O<sub>2</sub> gas showed a smaller tendency to buckle, but a larger tendency to whisker formation, than found during air exposure.

The lower growth rate and/or poorer adherence might be related to the subscale nitride formation which is known to occur during air exposure of Cr. However, similar observations in respect to differences in adherence and growth rate were made by Hänsel *et al.*<sup>40</sup> when comparing the behavior in Ar-H<sub>2</sub>-H<sub>2</sub>O with that in Ar-O<sub>2</sub>. Hultquist *et al.*<sup>41</sup> found the chromia growth rates at 900 °C to be approximately doubled in 2% water vapor (20 mbar) compared with the rate in dry oxygen at the same total pressure. A similar acceleration was observed when the Cr contained dissolved hydrogen prior to exposure.<sup>42</sup> The adhesion of the scale was improved when it was formed in water vapor-containing atmospheres, and this was proposed to be related to a greater fraction of scale growth at the metal-oxide interface. The fact that adherence of chromia-based scales formed in Ar/H<sub>2</sub>/H<sub>2</sub>O is better than those formed in air or oxygen was also observed by Malkow *et al.*<sup>43</sup> for a number of high-Cr ferritic steels.

At higher levels of water vapor (Ar-15% H<sub>2</sub>O), Henry *et al.*<sup>44</sup> observed that the growth rate of chromia on pure chromium at 900 °C was higher than in an Ar-15% oxygen gas mixture. The authors proposed that the increased rate of growth was due to enhanced inward scale growth as a result of the smaller ionic radius of OH<sup>-</sup> (95 pm) compared with that of O<sup>2-</sup> (140 pm). It was also found that scale adhesion was significantly improved when water vapor was present compared with the case for dry oxygen. Hänsel *et al.*<sup>45</sup> showed that for Cr oxidized at 1000 °C the oxidation rates in Ar-H<sub>2</sub>-H<sub>2</sub>O mixtures were equal or greater than those in Ar-O<sub>2</sub> or Ar-O<sub>2</sub>/H<sub>2</sub>O and the formation of blades was observed at the oxide surface. They proposed a model in which oxide growth in Ar-H<sub>2</sub>-H<sub>2</sub>O was sustained by diffusion of chromium vacancies and adsorption of H<sub>2</sub>O on oxide exposed to low oxygen-activity gas led to the formation of

hydroxyl species. At high oxygen activities, molecular oxygen adsorbs preferentially on the entire surface, overwhelming any local variation due to catalysis of H<sub>2</sub>O dissociation. This explained the absence of whiskers in high-oxygen-content atmospheres.

Figure 14 shows results of Michalik *et al.*<sup>15</sup> comparing weight-change data after isothermal exposures of Cr in various low- and high-*p*O<sub>2</sub> gases. Also shown are the weight changes after cooling to room temperature. The data confirm that samples oxidized in low-*p*O<sub>2</sub> gases (Ar-H<sub>2</sub>O and Ar-H<sub>2</sub>-H<sub>2</sub>O) generally showed, during cooling, far less extensive scale spalling than samples oxidized in high-*p*O<sub>2</sub> gas. The most pronounced spalling was found for the specimen oxidized in Ar-20% O<sub>2</sub>. Figure 15 shows transmission electron microscopy (TEM) micrographs from cross sections of specimens oxidized in Ar-20% O<sub>2</sub> and Ar-2% H<sub>2</sub>O at 950 °C for 0.5 h. The oxide scale formed in the high-*p*O<sub>2</sub> gas exhibits pores and cracks, mainly at the alloy-oxide interface. The oxide formed during oxidation in the low-*p*O<sub>2</sub> gas appears to be very dense, the alloy-oxide interface is intact and the oxide adheres well to the metal (Figure 15(b)).

Michalik *et al.*<sup>15,24</sup> carried out two-stage oxidation tests with Cr at 1000 °C where the gas was, without intermediate cooling, changed from Ar-O<sub>2</sub> to Ar-H<sub>2</sub>-H<sub>2</sub>O. An oxide layer with a morphology typical for scales formed in Ar-H<sub>2</sub>-H<sub>2</sub>O was found at the scale/metal interface, beneath the buckled layer grown in Ar-O<sub>2</sub>.

The oxidation of Cr and chromia-forming alloys in dry, high-*p*O<sub>2</sub> gases is known to be influenced by reactive evaporation at the scale/gas interface which releases CrO<sub>3</sub><sup>(g)</sup> as the primary species,<sup>6</sup> whereas in the low-*p*O<sub>2</sub> gas the partial pressure of volatile Cr species should be extremely low.<sup>11,12</sup> The differences in oxide growth rates observed in the various environments might thus be related to differences in the formation of volatile species in Ar-O<sub>2</sub> and Ar(-H<sub>2</sub>)-H<sub>2</sub>O (see Section 1.17.2.2). However, Michalik *et al.*<sup>15</sup> illustrated that, under the used experimental conditions, this effect could not explain the observed differences in scale growth rates.

#### 1.17.4.2.2 Oxidation of chromia-forming Fe- and Ni-based alloys

Essuman *et al.*<sup>46</sup> studied the isothermal oxidation behavior of FeCr alloys at 900 °C in Ar-O<sub>2</sub> and Ar-H<sub>2</sub>-H<sub>2</sub>O. Energy dispersive X-ray (EDX) analysis showed that the surface oxide scales formed in both test gases on Fe-20% Cr consisted essentially of chromia, and no indication for the presence of Fe in the scale

**Figure 14** Weight changes after 72 h isothermal oxidation and after subsequent cooling to room temperature of pure Cr in different high- and low- $p_{O_2}$  gases at 1000 °C. Reproduced from Michalik, M.; Hänsel, M.; Žurek, J.; Singheiser, L.; Quadackers, W. J. *Mater. High Temp.* **2005**, 22(3/4), 213–221.

**Figure 15** TEM cross sections of oxide scales formed on pure chromium after 0.5 h oxidation at 950 °C in (a) Ar-20% O<sub>2</sub> and (b) Ar-2% H<sub>2</sub>O. Reproduced from Michalik, M.; Hänsel, M.; Quadackers, W. J. Report Forschungszentrum Jülich, **67** (2007), ISBN 978-3-89336-486-2.

could be found. As described above for pure Cr, the chromia scale that formed in the Ar-H<sub>2</sub>-H<sub>2</sub>O gas exhibited a higher growth rate than that that formed in Ar-O<sub>2</sub>.

**Figure 16** shows gravimetric data during isothermal oxidation of a binary Ni-25Cr alloy in low- $p_{O_2}$  gases Ar-(4% H<sub>2</sub>)-7% H<sub>2</sub>O and in Ar-20% O<sub>2</sub>. The growth rate in the latter gas was smaller than that in the low- $p_{O_2}$  gases and the scale was found to have developed voids and internal pores at and near the oxide-alloy interface. In contrast, the oxide grown on this alloy in Ar-4% H<sub>2</sub>-7% H<sub>2</sub>O was compact and closely adherent to the substrate.<sup>47</sup> The latter phenomenon had already been found in the earlier studies of Wood *et al.*<sup>48</sup> for scales grown on Fe-28% Cr in Ar-10% H<sub>2</sub>O compared to scales grown in oxygen.

#### 1.17.4.2.3 Mechanisms of chromia scale growth

The differences in chromia growth in the various gases appear to be similar for all three discussed materials, that is, Cr as well as high-Cr Ni- and Fe-based alloys. The scales exhibit higher growth rates but are more compact, show better adherence and frequently exhibit a flatter metal/scale interface when formed in low- $p_{O_2}$  gas.

The better adherence of the oxide in the low- $p_{O_2}$  gases might be related to the H<sub>2</sub>O/H<sub>2</sub> bridges in voids described by Rahmel and Tobolski (see [Section 1.17.3.3](#)). In Ar-O<sub>2</sub> the outward-growing scale will result in vacancy condensation, preferentially at the alloy/oxide interface, resulting in poor

**Figure 16** Weight change versus time during isothermal oxidation of Ni-25Cr model alloy at 1050 °C in Ar-20% O<sub>2</sub>, Ar-7% H<sub>2</sub>O and Ar-4% H<sub>2</sub>-7% H<sub>2</sub>O. Reproduced from Essuman, E.; Meier, G. H.; Žurek, J.; Hänsel, M.; Norby, T.; Singheiser, L.; Quadakkers, W. J. *Corros. Sci.* **2008**, 50(6), 1753–1760.

adherence. The Rahmel–Tobolski mechanism provides an inward oxygen transport resulting in void healing and a net transport of the void away from the metal scale interface, which increases scale adherence. However, the mechanism cannot explain why, in fact, less voidage is seen in the scales formed in the low- $p_{\text{O}_2}$  gases (Figures 15 and 17).

The growth of chromia scales is generally believed to be controlled by boundary diffusion rather than lattice diffusion.<sup>37</sup> Nonetheless, if the mobile species are ionic and at local equilibrium with the surrounding oxide, then Wagner's description<sup>6,49</sup> of the dependence on  $p_{\text{O}_2}$  of scale growth rate can be applied, providing that a suitable effective diffusion coefficient is used. If the predominant defects are fully charged vacancies, then it is predicted for the parabolic rate constant  $k_p$ <sup>49</sup>

$$k_p \approx \text{const}(p_{\text{O}_2})^{\frac{1}{16}} \quad [12]$$

However, if the principal defects are interstitials and the ambient  $p_{\text{O}_2}$  value is significantly above the Cr/Cr<sub>2</sub>O<sub>3</sub> equilibrium value, then  $k_p$  is independent of  $p_{\text{O}_2}$ . Both predictions are not in agreement with the experimental observations.

From the TEM cross sections of the oxidized Cr (Figure 15) and Ni-25Cr specimens (Figure 17), it is apparent that the oxide scales formed in the high- $p_{\text{O}_2}$  gas show large grains with a columnar morphology which is typical, as frequently described by several authors,<sup>50</sup> for scales that mainly grow by outward cation diffusion. The oxides formed in the two low- $p_{\text{O}_2}$  gases are, however, extremely fine grained with a

small tendency for the grain size to increase towards the scale/alloy interface.

Figure 18 shows the distribution of oxygen isotopes in the scale formed on alloy Ni-25Cr during the two-stage oxidation in Ar-H<sub>2</sub>-H<sub>2</sub><sup>16</sup>O/H<sub>2</sub><sup>18</sup>O at 1050 °C. The small <sup>18</sup>O peak at the scale/alloy interface is a clear proof of inward transport of oxygen-bearing species along rapid diffusion paths, likely grain boundaries.<sup>51</sup> The continuously decreasing <sup>18</sup>O concentration in the outer part of the scale is, at least partly, related to extensive isotope exchange between <sup>18</sup>O at the grain boundaries and <sup>16</sup>O within the grains due to the extremely fine size of the chromia grains.<sup>51</sup> A similar difference in growth mechanism in a low- and high- $p_{\text{O}_2}$  environment was also found by Bamba *et al.*<sup>52</sup> for the alloy Fe-15Cr-0.5 Si at 850 °C.

In earlier studies it was proposed that the better adherence of chromia scales on pure chromium formed in water vapor-containing atmosphere may be related to enhanced scale plasticity.<sup>53,54</sup> It would seem that in terms of defect concentration the main effect of water vapor is to increase the concentration of the majority species so that one might not expect to see an effect on creep rates.<sup>27</sup> The improved plasticity in the low  $p_{\text{O}_2}$  gas could be related to the smaller chromia grain size compared to that formed on chromia in dry atmospheres. However, on the basis of the newer results, a more likely explanation is that the observed differences in adherence as well as growth rate of the scales found in the high- and low- $p_{\text{O}_2}$  gases are just a result of the difference in scale growth mechanisms. By the substantial inward

**Figure 17** TEM cross sections of oxide scales formed on Ni-25Cr model alloy during 4 h oxidation in (a) Ar-20% O<sub>2</sub> and (b) Ar-4% H<sub>2</sub>-2% H<sub>2</sub>O at 1050 °C.

**Figure 18** Semi-logarithmic plot of the <sup>18</sup>O and <sup>16</sup>O profiles in the oxide scale on a Ni-25Cr model alloy after two-stage oxidation at 1050 °C: first stage 0.5 h in Ar-4% H<sub>2</sub>-2% H<sub>2</sub><sup>16</sup>O; second stage 2 h in Ar-4% H<sub>2</sub>-2% H<sub>2</sub><sup>18</sup>O. Reproduced from Żurek, J.; Young, D. J.; Essuman, E.; Hänsel, M.; Penkalla, H. J.; Niewolak, L.; Quadakkers, W. J. *Mater. Sci. Eng. A* **2008**, 477, 259–270.

oxygen transport in the low- $p_{\text{O}_2}$  gas, growth of voids as a result of vacancy condensation at the scale–metal interface is suppressed, resulting in better scale adherence. The extremely high grain boundary density favors inward oxygen transport, resulting in a higher oxide growth rate in the low- $p_{\text{O}_2}$  gas.

The remaining questions concern the mechanism whereby H<sub>2</sub>O<sup>(g)</sup> alters the grain size in the low- $p_{\text{O}_2}$  gas and the way in which inward oxygen transport occurs.<sup>37</sup> One possibility is that the presence of H<sub>2</sub>O adsorbed at the oxide grain boundaries hinders

their movement and thus grain growth. This would explain the extremely fine oxide grains formed in Ar(–H<sub>2</sub>)–H<sub>2</sub>O.<sup>51</sup> However, it could also be argued that the stronger contribution of inward scale growth might not be the result of the finer grain size: rather, the finer grain size could result from the modified scale growth process induced by H<sub>2</sub>O<sup>(g)</sup>. The available results do not allow a distinction to be drawn between the two possibilities. Nonetheless, it is clear that the effect of water vapor during oxidation in Ar(–H<sub>2</sub>)–H<sub>2</sub>O environments is twofold: water molecules

incorporated into the scale provide accelerated mass transport while simultaneously promoting the formation of a fine-grained, inwardly growing, and therefore better adhering, oxide scale.

#### 1.17.4.2.4 Commercial chromia-forming Fe- and Ni-based alloys

Nearly all commercially available chromia-forming alloys contain intentionally added alloying elements and impurities which may substantially affect the oxidation mechanisms and thus also differences in oxidation behavior in the mentioned low and high- $p_{O_2}$  gases. The alloying elements and impurities may, for example, lead to doping of the chromia layer and/or result in formation of other mixed oxides, for example, of the spinel type. Only a few systematic studies that deal with the effect of such impurities and minor alloying additions on the differences in the oxidation behavior in low- and high- $p_{O_2}$  gases are available.

England and Virkar<sup>55,56</sup> studied the oxidation of a series of thin-foil nickel-based alloys (Inconel 625, Inconel 718, Hastelloy X, and Haynes 230) in air and wet hydrogen ( $p_{O_2} = 10^{-21}$  to  $10^{-16}$  atm,  $p_{H_2O} = 0.07$  atm) at 700–1100 °C. At 800 °C the oxidation rate in wet hydrogen was increased by factors ranging between 8 and 30, but at 1100 °C the effect of wet hydrogen was to decrease the oxidation rate compared to that in air by factors ranging between 1.5 and 13. Hussain *et al.*<sup>57,58</sup> reported that Hastelloy C-4 formed a protective scale in 100% steam at all temperatures in the range 600–1200 °C, whereas the scale spalled when formed in air.

Extensive studies concerning the behavior of chromia forming-alloys, especially high-Cr ferritic steels, in low- and high- $p_{O_2}$  gases have been carried out in the development of solid oxide fuel cells

(SOFCs), as in these devices metallic interconnects are exposed on one side to the oxidant gas (mostly air) and on the other side to moist hydrogen-based environments. Figure 19 shows the oxide scales on a high-Cr ferritic steel Crofer APU (nominal composition in mass%, 22Cr–0.5Mn–Ti–La) after exposure for 1000 h at 800 °C in air and Ar–H<sub>2</sub>–H<sub>2</sub>O. In both cases a two-layered scale is formed consisting of Cr<sub>2</sub>O<sub>3</sub> and an outer Cr/Mn-spinel. During air exposure the spinel is present in the form of well-developed crystals, whereas in Ar–H<sub>2</sub>–H<sub>2</sub>O it possesses a blade-like morphology (Figure 20). The scale formed in the low- $p_{O_2}$  gas tends to form voids at/near the interface between the chromia and the spinel layer (Figure 19). Traces of Ti are frequently present in the scales: that is, dissolved in the Cr<sub>2</sub>O<sub>3</sub> near the scale–alloy interface and in form of TiO<sub>2</sub> particles near the scale–gas interface.<sup>59,60</sup> Presence of minor concentrations of Al and Si (a few tenths of a percent) results in internal oxide precipitates of those elements in the subsurface layer. In some cases the oxides contain traces of reactive elements (REs), for example, La or Y, which are added to the ferritic steels in metallic form or in the form of an oxide dispersion to lower the oxidation rates and/or improve the scale adherence.<sup>53,54</sup>

Contrary to the cases described in the previous section, the Cr-rich surface scales on the ferritic steel show a slightly slower growth rate in low- than in high- $p_{O_2}$  gas (Figure 19). This is in agreement with findings of other authors,<sup>60,61</sup> who observed that the growth rates of Cr-rich oxide scales on high-Cr ferritic steels at 800–900 °C in the H<sub>2</sub>/H<sub>2</sub>O-based gases are similar to, or smaller than, in air. The reason why these ferritic steels behave, in respect to gas composition dependence of the oxidation rate,

**Figure 19** SEM cross sections of high-Cr ferritic steel Crofer 22 APU after 1000 h oxidation at 800 °C in air and Ar–H<sub>2</sub>–H<sub>2</sub>O.<sup>59,60</sup>

**Figure 20** Surface scale morphologies of high-Cr ferritic steel Crofer 22 APU after 1000 h exposure at 800 °C in air and Ar-H<sub>2</sub>-H<sub>2</sub>O. Adapted from Piron-Abellan, J.; Quadakkers, W. J. Report Forschungszentrum Jülich, Jül-4170, 2005; ISSN 0944-2952.

differently from that of Cr and model alloys of the type NiCr and FeCr (see [Sections 1.17.4.2.1](#) and [1.17.4.2.2](#)) cannot be unequivocally derived from the mentioned SOFC-related studies. Also, the differences in behavior mentioned above for the commercial Ni-based alloys are not immediately apparent from the respective papers. A likely explanation is that a change in scale growth mechanism imparted by one or more of the mentioned minor alloying additions (Mn, Ti, Si, Al, rare earths) results in a change of the gas composition dependence of the oxidation rate. Therefore, possible effects of some common minor alloying additions on the scale formation of chromia-forming alloys in low- and high- $p_{\text{O}_2}$  gases will be discussed in the following section.

#### 1.17.4.2.5 Effect of common minor alloying additions

**Figure 21** shows weight change data of a number of ternary Ni-25Cr-based model alloys in low- and high- $p_{\text{O}_2}$  gas after isothermal exposure at 1050 °C. Also presented are the weight changes after subsequent cooling to room temperature. The data shows that Y reduces, as frequently demonstrated,<sup>53,54</sup> the scale growth rate and spallation from the NiCr alloy during oxidation in Ar-O<sub>2</sub>. However, the Y addition has hardly any effect on the growth rate in the low- $p_{\text{O}_2}$  gas. The measured weight changes in this gas are even slightly higher than those of the corresponding Y-free alloy, which was found to be related to an additional oxygen uptake due to internal Y oxidation.<sup>51</sup> Like Ni-25Cr, the Ni-25CrY alloy showed a substantially higher oxide growth rate in Ar-H<sub>2</sub>O-H<sub>2</sub> than in Ar-O<sub>2</sub>. Apparently, the reactive element addition does not fundamentally alter the atmosphere dependence observed for Cr,

NiCr, and FeCr. This is in agreement with recent results from Essuman *et al.*,<sup>46</sup> who found for an Y<sub>2</sub>O<sub>3</sub> dispersion strengthened Ni-Cr-based alloy a similar atmosphere dependence of the oxidation rate as observed for Ni-25Cr.

The decreased growth rate and improved adherence of chromia scales grown in air and other oxygen-rich environments due to the Y addition is commonly explained by a reduction of outward cation diffusion as a result of Y segregation to the oxide grain boundaries.<sup>54</sup> The predominant inward grain boundary oxygen transport in combination with the high grain boundary density of the scales formed in Ar-4% H<sub>2</sub>-7% H<sub>2</sub>O ([Section 1.17.4.2.3](#)) has the result that Y-addition to the Ni-Cr alloy does not substantially alter the scale growth rate, unlike the effect observed during oxidation in O<sub>2</sub>-rich environments.

Mn addition apparently enhances the oxidation rate and decreases the scale adherence during Ar-O<sub>2</sub> exposure, but it decreases the growth rate in Ar-H<sub>2</sub>-H<sub>2</sub>O (**Figure 21**).<sup>51</sup> Similar low oxidation rates of the Mn-containing alloys were found during exposure in Ar-CO-CO<sub>2</sub>,<sup>62</sup> thereby indicating that the underlying mechanism is related to the low- $p_{\text{O}_2}$  rather than the presence of water vapor and/or hydrogen. The ternary NiCrMn alloy formed a double-layered oxide scale consisting of Cr<sub>2</sub>O<sub>3</sub> and a thin layer of Cr/Mn spinel in the outer part of the scale. In the case of Ar-20% O<sub>2</sub> exposure, the spinel layer was slightly thinner than that formed in Ar-4% H<sub>2</sub>-7% H<sub>2</sub>O; additionally, NiO was locally observed. The oxide scale formed on alloy NiCrMnY had a morphology similar to that on alloy NiCrMn; however, no clear indication of Ni-containing oxide was found during Ar-O<sub>2</sub> exposure, and the scale adherence was dramatically improved.

These results strongly indicate that the atmosphere dependence of the oxidation rate of the NiCrMn alloy and also that described in the previous section for the high-Cr ferritic steels are related to the formation of the Cr/Mn spinel on top of the chromia scale. Manganese has a higher solubility in  $\text{Cr}_2\text{O}_3$  at high oxygen potentials than at low  $p_{\text{O}_2}$  values.<sup>63</sup> One might speculate that in the low- $p_{\text{O}_2}$  gas Mn hinders inward oxygen transport by segregating at oxide grain boundaries. As far as known to the authors, this effect has not been studied extensively and no unequivocal evidence could be derived from previous work. Grain boundary segregation of Mn in the scale formed in the low- $p_{\text{O}_2}$  gas is not unlikely, considering the large size of the  $\text{Mn}^{+2}$  ion compared to that of  $\text{Cr}^{+3}$ .

On the basis of the phase diagrams (Figure 22) of Naoumidis *et al.*,<sup>63</sup> the spinel phase formed in the low- $p_{\text{O}_2}$  gas is stoichiometric  $\text{MnCr}_2\text{O}_4$ , whereas in high- $p_{\text{O}_2}$  gas it is  $\text{Mn}_{1+x}\text{Cr}_{2-x}\text{O}_4$ . This is confirmed by the secondary neutral mass spectrometry (SNMS) results in Figure 23 showing a nearly constant Cr/Mn ratio in the outer part of the oxide scale after exposure of a Mn-containing, high-Cr ferritic steel in  $\text{Ar-H}_2\text{-H}_2\text{O}$  but a changing ratio as function of depth, and thus as function of  $p_{\text{O}_2}$ , when formed in air. Retaining the double-layered oxide structure during longer time exposure in  $\text{Ar-H}_2\text{-H}_2\text{O}$  would require a balanced flux of Cr and Mn ions through the oxide scale. If, because of the low Mn concentration in the alloy the flux of Mn is reduced after longer

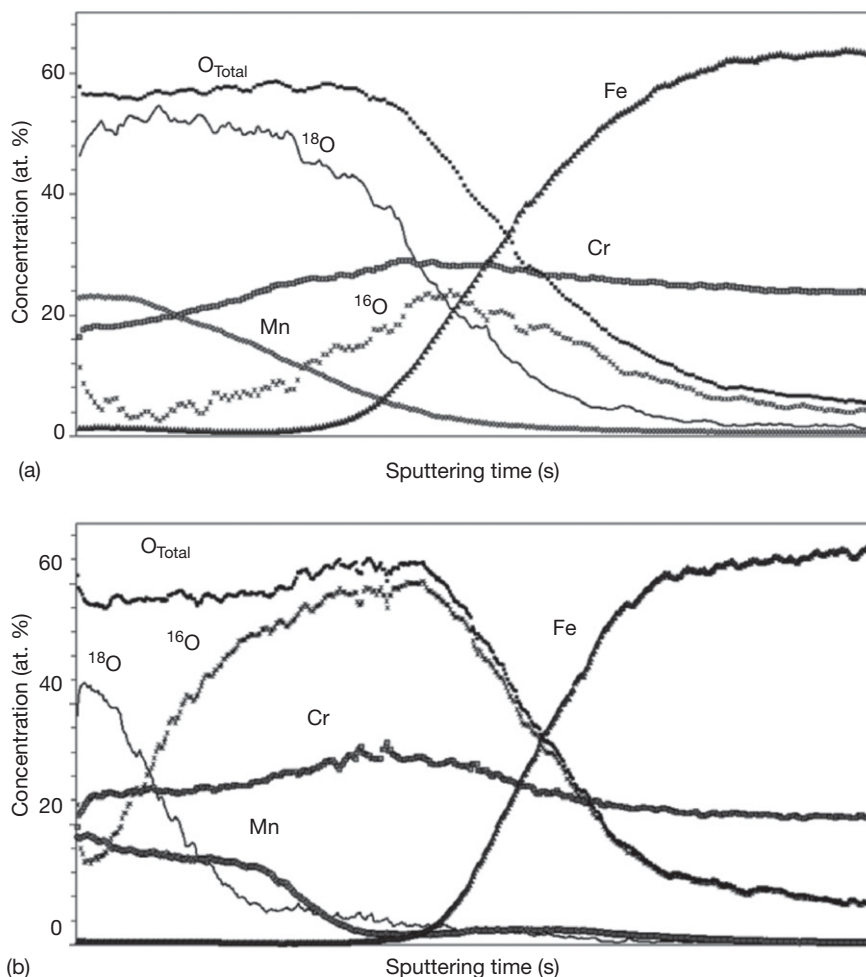

**Figure 21** Weight changes of Ni-25Cr-based model alloys after isothermal exposure at 1050 °C and after subsequent cooling to room temperature in (a) Ar-20%  $\text{O}_2$  and (b) Ar-4%  $\text{H}_2$ -7%  $\text{H}_2\text{O}$ . Reproduced from Ertl, S. T. Diss. RWTH Aachen, 2006.

exposure times,<sup>61</sup> a Mn deficit will occur in the spinel layer. In the  $p_{\text{O}_2}$  gradient existing in the scale, this will result in a vacancy flux from the spinel surface towards the spinel–chromia interface. Here these vacancies tend to condense and result in void formation, as illustrated in Figure 19. In air, the Mn deficit in the spinel may be compensated by Cr cations from the inner chromia layer. This would result in an enhanced outward flux of Cr, which could explain why during air exposure the presence of Mn in the alloy increases not only the overall thickness of the oxide but also that of the inner chromia scale.<sup>51</sup>

It should be mentioned that the rapid incorporation of Mn into the oxide layer may easily lead to complete exhaustion of the Mn reservoir in the test specimen. This effect, which will be especially pronounced at high oxidation temperatures and/or when

using thin components,<sup>61</sup> will obviously alter the described effect of Mn additions on the gas composition dependence of the oxide growth kinetics.

Figure 24 shows metallographic cross sections of a high-Cr ferritic steel with a very similar composition as that shown in Figure 19 but with minor additions of Si and Al, after exposure in air and  $\text{H}_2/\text{H}_2\text{O}$  at 800 °C. The volume increase accompanied by the internal oxide formation leads to outward metal flow<sup>61,64</sup> resulting in formation of metallic nodules in the scale and damage of the oxide scale.<sup>61</sup> In spite of this difference in scale morphology compared to that shown in Figure 19, both steels exhibit a double-layered surface oxide of  $\text{Cr}_2\text{O}_3$  and Cr/Mn spinel that exhibits a slightly higher growth rate in high – than in low –  $p_{\text{O}_2}$  gas. Apparently, the atmosphere dependence is mainly governed by presence of the Cr/Mn spinel and is not

**Figure 24** Metallographic cross sections of high-Cr ferritic steel Crofer 22 A after 1000 h exposure in Air and in Ar-4% H<sub>2</sub>-2% H<sub>2</sub>O at 800 °C. The steel had a very similar composition as that shown in Figure 19; however, it contained 0.1% Al and 0.1% Si.

fundamentally affected by presence of the minor alloying additions (0.1%) of Al and Si. This may be different if higher amounts (e.g., a few tenths of a percent) of Si/Al are present. In that case, a more extensive internal oxidation and formation of metallic protrusions result in a more severe damage of the external scale with the result that molecular transport substantially contributes to the scale growth process.<sup>61</sup> It is obvious that then a substantially different atmosphere dependence may occur. This can be derived from results of Hammer *et al.*,<sup>65</sup> who studied the behavior of high-Cr ferritic steels containing Al and/or Si up to 1 wt% in low- and high- $p_{O_2}$  gas between 700 and 900 °C. For such alloys the gas composition dependence described earlier for alloys forming ‘ideal’ gas-tight two-layered spinel/chromia layers is not clearly observed.

Further studies on the effect of minor alloying additions on the oxidation behavior in low- and high- $p_{O_2}$  gases were carried out by Galerie *et al.*<sup>14</sup> The authors investigated the behavior of 18% Cr ferritic steels containing minor additions of Nb or Ti. Both elements affected the growth rate of the protective scale but did not fundamentally alter the relative differences between Ar-O<sub>2</sub> and Ar-H<sub>2</sub>O exposure.

#### 1.17.4.3 Effect of Environment on Scale Formation in Case of ‘Borderline Alloys’

##### 1.17.4.3.1 Nonprotective oxidation in water vapor

For iron–chromium alloys with intermediate Cr content in the range 8–20%, it has frequently been found that oxidation rates in water vapor may be several orders of magnitude higher than those found under

dry conditions.<sup>6,16,22,49,66–68</sup> These high rates are related to a change in oxide composition from a chromia base to an Fe-oxide base scale. They are sometimes preceded by an initial period of protection after which breakaway oxidation occurs as a consequence of failure of the protective chromium-rich oxide layer. Referring to Figure 13, the critical Cr content required for obtaining protective chromia scale formation in water vapor is thus higher than that required during O<sub>2</sub> or air exposure.

Ehlers *et al.*<sup>4</sup> suggested that during exposure of 9% Cr steels, in Ar-50% H<sub>2</sub>O at 600–650 °C, volatile Fe(OH)<sub>2(g)</sub> may form in the inner layers of the scale which is then converted to hematite or magnetite in the outer layers of the scale thereby contributing to the deterioration of the protective Cr-rich oxide. However, based on the available thermodynamic data, the vapor pressure of the hydroxide may be too low to provide sufficient mass transport by the volatile species.<sup>16</sup> Galerie *et al.*<sup>14</sup> showed that the first stage of breakaway of Fe-15% Cr at 800–1000 °C in Ar-15% H<sub>2</sub>O corresponds to a separation of the chromia scale from the alloy and consequently scale equilibration, allowing the formation of hematite at the metal–oxide interface. Then rapid growth of hematite at this interface disrupts the chromia scale and breakaway is initiated. The authors propose that the more acidic nature of hematite compared to chromia encourages more rapid dissociation of water and therefore continued hematite growth is favored, whereas in the absence of water vapor chromia would continue to form and protection is maintained. Fujii and Meussner<sup>68</sup> oxidized a range of FeCr alloys with up to 25% Cr at temperatures between 700 and 1100 °C in Ar-10% water vapor and observed a period of protective oxidation before occurrence of high

oxidation rates for the alloys with a Cr content greater than 20%. They proposed that the high rates of oxidation were related to hydrogen/water dissociation in pores (see [Section 1.17.3.3](#)) within the wüstite layer. Mikkelsen and Linderöth<sup>67</sup> explained the breakaway oxidation of Fe–22% Cr at 800 °C in a H<sub>2</sub>/Ar gas mixture (7:93) with addition of 12% water vapor to be the consequence of the stability of fast-growing wüstite, whereas with 1% water vapor wüstite is not stable. Hayashi *et al.*<sup>69</sup> observed for diluted Fe–Al alloys a very similar gas composition dependence as observed for Fe–Cr alloys by other authors.

Summarizing, it can be said that the breakaway type oxidation of ‘borderline’ FeCr-based alloys with intermediate contents of protective scale-forming elements exhibits a number of common features which strongly indicates that the responsible process is independent of the type of oxide formed. The mechanisms occurring at high temperatures (700–1000 °C) seem to be not fundamentally different from those at lower temperature (500–650 °C). Modified transport processes in, for example, wüstite due to presence of water vapor have clearly been verified, but are unlikely to be responsible for the initiation of breakaway because it also occurs at temperatures at which wüstite is unstable. A mechanism that explains the breakaway oxidation at higher as well as lower temperature will be discussed in the following sections.

#### 1.17.4.3.2 Internal oxidation of Cr as trigger for breakaway oxidation

**Figure 25** shows SEM cross sections of an Fe–10Cr model alloy after isothermal oxidation for 72 h at 900 °C in Ar–20% O<sub>2</sub>, Ar–4% H<sub>2</sub>–2% H<sub>2</sub>O and Ar–7% H<sub>2</sub>O. In Ar–O<sub>2</sub> the scale contains substantial amounts of Fe and consists of Fe<sub>2</sub>O<sub>3</sub> near the scale–gas interface, an intermediate layer of spinel, and a thin chromia layer in contact with the alloy. Apparently, significant transient oxidation occurred before the chromia became continuous, and thus Fe–10Cr can be considered as a ‘borderline alloy’ when exposed to Ar–O<sub>2</sub>.<sup>70</sup> In Ar–H<sub>2</sub>–H<sub>2</sub>O, only internal oxides, mainly of Fe/Cr spinel, have formed.<sup>62</sup> Very rapid oxidation occurred in Ar–H<sub>2</sub>O because the oxide scale consisted mainly of Fe-rich oxides. Similar observations were made at 1050 °C.<sup>46</sup>

These results clearly show that internal oxidation of Cr is promoted in the gases containing water vapor. In the gas with the highest oxygen potential (Ar–20% O<sub>2</sub>), a continuous external chromia layer develops

despite the presence of transient oxides. In the gas with the lowest oxygen potential (Ar–H<sub>2</sub>–H<sub>2</sub>O), the Cr is oxidized internally and no external Fe oxide scale is formed because of the low oxygen activity in the gas (**Figure 2**). This is contrary to Ar–H<sub>2</sub>O in which the alloy matrix, which is Cr-depleted due to the internal oxidation, oxidized because of the higher  $p_{O_2}$ , resulting in non-protective scale formation. A similar effect of water vapor on internal oxidation was found by Ani *et al.*<sup>71</sup> These authors studied the behavior of FeCr alloys at 800 °C in dry and wet gas ( $p_{H_2O} = 3 \times 10^{-3}$  bar) at a fixed low  $p_{O_2}$  of  $1.1 \times 10^{-9}$  bar. The transition from internal to external oxidation was shifted from 8% Cr in the dry gas to 12% Cr in the wet gas. In low Cr alloys, the depth of internal oxidation in the wet gas was substantially larger than in the dry gas.

These results thus indicate that the inward flux of oxygen in the FeCr alloys is greater in the water vapor-containing gases than in the dry gases. It is well known that hydrogen from water vapor readily permeates ferritic steels at high temperatures. Rahmel and Tobolski<sup>36</sup> observed hydrogen uptake in the samples oxidized in wet gases. Also a ‘dual atmosphere’ effect has been observed for ferritic steel interconnects in SOFCs where the oxidation on the cathode (air) side is influenced by the presence of a hydrogen/water vapor mixture on the anode (fuel) side.<sup>72</sup> Furthermore, the intrinsic diffusivity of hydrogen in bcc iron at 900 °C is approximately  $4 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$ ,<sup>73</sup> which is 3 orders of magnitude larger than that of oxygen, which is  $2 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ .<sup>74</sup> The values in fcc iron are  $7 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  for hydrogen<sup>75</sup> and  $1.8 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$  for oxygen.<sup>74</sup>

The reasons for the enhanced internal Cr oxidation by hydrogen incorporation into the alloy will now be discussed.

#### 1.17.4.3.3 Conditions for external chromia formation in dry and wet gases

The development and maintenance of a continuous external chromia scale require that two criteria are satisfied. First, the Cr concentration in the alloy must exceed that necessary for outward diffusion to prevent internal oxidation.<sup>76</sup> This criterion for the case of Fe–Cr alloys is:

$$N_{Cr}^{(1)} > \left[ \frac{\pi g^*}{3} N_O^{(S)} \frac{D_O V_m}{\tilde{D}_{Fe-Cr} V_{CrO_{1.5}}} \right]^{1/2} \quad [13]$$

where  $N_O^{(S)}$  is the oxygen solubility in the alloy,  $D_O$  is the diffusivity of oxygen in the alloy,  $\tilde{D}_{Fe-Cr}$  is the alloy

interdiffusion coefficient, and  $V_m$  and  $V_{CrO_{1.5}}$  are the molar volumes of the alloy and oxide, respectively. It was assumed here that the internal oxide was chromia. The factor  $g^*$  is generally approximated as about 0.3.<sup>77</sup> Equation [13] was derived under conditions where only Cr could oxidize. Under conditions where both Fe and Cr can oxidize, the transient oxidation of Fe must also be considered. Gesmundo and Viani<sup>78</sup> showed that the critical solute concentration increases as the rate constant for the growth of the transient, nonprotective oxide increases.

The second criterion is that, once a continuous external scale is formed, diffusion in the alloy must be rapid enough to supply the solute at least at the rate it is being consumed by scale growth.<sup>79</sup> This criterion may be expressed as:

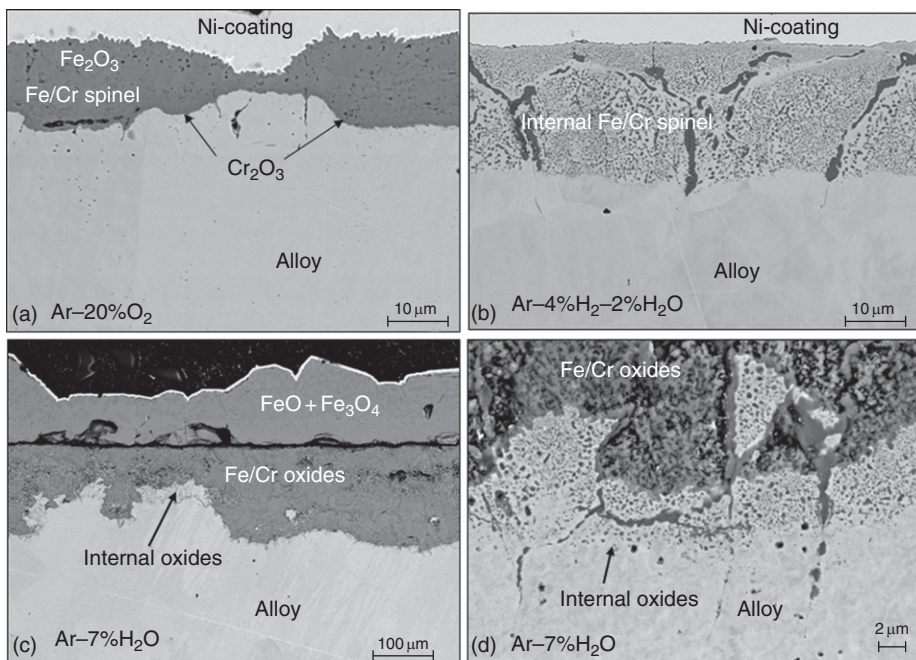

$$N_{Cr}^{(2)} = \frac{V_m}{32v} \left( \frac{\pi k_p}{\tilde{D}_{Fe-Cr}} \right)^{1/2} \quad [14]$$

where  $k_p$  is the parabolic rate constant for growth of the external scale, measured in terms of scale thickness. Based on data Essuman *et al.*<sup>46</sup>, it was derived that, for example, at 900 °C  $N_{Cr}^{(1)}$  for FeCr alloys is  $\sim 0.03$ . Comparison of the results in Figures 25–27 shows that for the FeCr alloys the critical Cr content for external scale formation in Ar–20% O<sub>2</sub> at 900 °C is near 10 mass% ( $N_{Cr}^{(1)} \approx 0.11$ ). In Ar–H<sub>2</sub>–H<sub>2</sub>O, that

is, a gas in which Fe oxide can hardly form, it is apparently between 10 and 20 mass% ( $N_{Cr}^{(1)}$  between 0.11 and 0.21). In the wet gas Ar–H<sub>2</sub>O, in which Fe can easily oxidize, it is larger than 20 mass% ( $N_{Cr}^{(1)} > 0.21$ ).

Essuman *et al.*<sup>80</sup> have shown that for FeCr alloys the parameter regarding internal oxidation  $N_{Cr}^{(1)}$  (eqn [13]) moves to higher values as the temperature is increased (see Figure 27). Figure 27 shows that this is indeed the case for exposure in Ar–O<sub>2</sub> as well as in Ar–H<sub>2</sub>O. Thus, for Fe–20Cr, non-protective oxidation occurs in both gases at 1050 °C, only in Ar–H<sub>2</sub>O at 900 °C and in none of the gases at 800 °C.

Consideration of eqn [13] indicates that promoting internal oxidation by dissolution of hydrogen could result from a reduction of  $\tilde{D}_{Fe-Cr}$ ; however, based on data of Park *et al.*<sup>81</sup>, this seems to be unlikely. The second possibility is that water vapor is increasing the effective value of  $N_O^{(S)}$ . The rapid diffusion of hydrogen into the specimen may shift the H–O–H<sub>2</sub>O equilibrium such that a metastably high concentration of oxygen exists at the specimen surface and results in an increased inward flux of oxygen.<sup>46</sup> Considering the equilibration of water vapor at the specimen surface

**Figure 25** Cross-section SEM micrographs of Fe–10Cr model alloy after isothermal oxidation for 72 h at 900 °C in various atmospheres: (a) Ar–20% O<sub>2</sub>; (b) Ar–4% H<sub>2</sub>–2% H<sub>2</sub>O; (c) Ar–7% H<sub>2</sub>O; (d) Ar–7% H<sub>2</sub>O high magnification of the internal oxidation zone in Fig. (c). Note the differences in magnification.<sup>46,62</sup>

[46,62](#)

**Figure 27** Weight changes after 72 h isothermal oxidation of a binary Fe-20Cr model alloy in Ar-O<sub>2</sub> and Ar-H<sub>2</sub>O at different temperatures. Reproduced from Essuman, E.; Meier, G. H.; Žurek, J.; Hänsel, M.; Singheiser, L.; Quadakkers, W. J. *Mater. Sci. Forum* **2008**, 595–598, 699–706.

the concentration of oxygen at the metal surface may be expressed as:

$$N_{\text{O}} = K_{15} \frac{p_{\text{H}_2\text{O}}}{N_{\text{H}}^2} \quad [16]$$

If the hydrogen concentration is reduced by rapid inward diffusion, the gas phase will establish an increased concentration of dissolved oxygen, resulting in a concomitantly higher inward oxygen flux.

The final possibility is that the dissolved hydrogen increases the diffusivity of oxygen. It is known from studies on austenitic iron that lattice distortion produced by interstitials can affect diffusivities. For example, the intrinsic diffusivity of carbon increases with increasing carbon content, which is usually interpreted in terms of carbon interstitials expanding the Fe lattice and thus increasing their own mobility.<sup>82</sup> It is conceivable that the rapidly diffusing hydrogen interstitials expand the iron lattice sufficiently so that the diffusivity of the larger oxygen interstitials is increased.

#### 1.17.4.3.4 Breakaway oxidation mechanisms of FeCr alloys in water vapor

As stated in Section 1.17.4.3.1, enhanced, breakaway type oxidation of 'borderline' Fe(Ni)Cr-based alloys in water vapor-containing environments has been described in a large number of publications as well as in textbooks.<sup>1,6</sup> If enhanced internal oxidation of Cr due to dissolution of hydrogen in the alloy is the main reason for the occurrence of breakaway oxidation in steam or Ar–H<sub>2</sub>O, then this process will be promoted if molecules of water vapor or hydrogen have direct access to the steel surface. The significance of molecular transport of water vapor was identified by several authors as an important factor for the occurrence of breakaway in O<sub>2</sub>/H<sub>2</sub>O mixtures.<sup>16</sup> Ikeda *et al.*<sup>83</sup> proposed molecular transport as a major pre-requisite for the breakdown of initially protective scales on 5–30% Cr steels in O<sub>2</sub>–10 vol.% H<sub>2</sub>O at 750 and 900 °C. Similar conclusions were derived by Ehlers *et al.*<sup>16</sup> from thermogravimetry studies of a 9% Cr steel, where the gas was in situ changed from dry Ar–1% O<sub>2</sub> to an Ar–1% O<sub>2</sub>–7% H<sub>2</sub>O mixture at 650 °C. Galerie *et al.*<sup>14,32</sup> proposed that the change from a protective oxide scale formed in dry gas into breakaway-type oxidation of an Fe–15% Cr alloy at 800–1000 °C during subsequent exposure in wet gas was initiated by molecular transport of water vapor via microcracks.

In many of the studies in which Fe-rich, breakaway-type oxide scales were observed during exposure of Fe–Cr alloys in water vapor, a zone with internal precipitates of Cr-rich oxide was found (see Figure 25 and, e.g., Ueda *et al.*<sup>84</sup>). In classical oxidation theory, the presence of this zone can be described as a logical consequence of the formation of the nonprotective Fe-based oxide scale; that is, the oxygen partial pressure below that scale at the scale–alloy interface is sufficiently high for Cr to become

oxidized internally. Ehlers *et al.*<sup>4,16</sup> showed that an internal oxidation zone was present after 250 h oxidation of a 9% Cr steel in Ar–50% H<sub>2</sub>O at 650 °C. After subsequent exposure of the specimen in air, this internal oxidation zone vanished and a thin, protective, Cr-rich layer was formed at the scale–alloy interface and the scale growth rate in this second oxidation stage was extremely small. This change in composition and morphology of the inner interface upon changing from water vapor to a high-*p*O<sub>2</sub> atmosphere or vice versa can be explained by changes in transport processes in the scale by one or more of the mechanisms described in Section 1.17.3. However, based on the discussions in the previous sections, the main change in oxidation mechanism that occurs when changing from water vapor to a high-*p*O<sub>2</sub> gas is the decreased tendency of Cr to become internally oxidized. The formation of the rapid, breakaway-type, Fe-rich oxide scales when exposing 'borderline alloys' in water vapor is just a result of Cr depletion in the alloy matrix because Cr oxidizes internally rather than in the form of a protective external scale. This mechanism would be promoted by a direct reaction of H<sub>2</sub>O(g) molecules with the metal surface, thus explaining the observations described above that transport of H<sub>2</sub>O(g) through a preexisting scale is required to initiate breakaway oxidation. In H<sub>2</sub>O(g)/O<sub>2</sub>(g) mixtures, competitive adsorption of oxygen and water vapor molecules at external and internal surfaces of the oxide scale was found to govern the growth of the Fe-rich oxide scales at high H<sub>2</sub>O/O<sub>2</sub> ratios. It would therefore be expected that occurrence of breakaway oxidation is determined by the H<sub>2</sub>O(g)/O<sub>2</sub>(g) ratio in the gas, as was indeed experimentally observed for a 9% Cr steel at 600 °C.<sup>16</sup> Also, the oxidation behavior of Fe–Al alloys with Al contents of 5 wt% was found to depend on the H<sub>2</sub>O(g)/O<sub>2</sub>(g) ratio.<sup>85</sup>

#### 1.17.4.3.5 Borderline NiCr alloys in water vapor

Essuman *et al.*<sup>47</sup> studied the oxidation behavior of Ni–25Cr and Ni–20Cr as well as the 'borderline alloy' Ni–10Cr in various dry and wet Ar-based gas mixtures. Decreasing the oxygen content in dry gas from 20% to 1% was found to promote the selective oxidation of Cr in the 'borderline alloy' Ni–10Cr. It could be shown that this is related to a decrease of the NiO growth rate with decreasing oxygen partial pressure (Figure 28), which, according to Gesmundo

**Figure 28** Weight change versus time during isothermal oxidation of pure Ni at 1050 °C in Ar-20% O<sub>2</sub>, Ar-1% O<sub>2</sub> and Ar-7% H<sub>2</sub>O.

*et al.*,<sup>78</sup> promotes selective oxidation of Cr. Exposure in Ar-H<sub>2</sub>O would then be expected to result in a further improvement in selective oxidation due to the very slow growth rate of NiO in this low- $p_{O_2}$  gas.<sup>32</sup> However, the Cr-rich surface scale formed in Ar-H<sub>2</sub>O contained Ni-rich oxide. Also, internal oxides of Cr could be found. These results clearly indicated that, like in FeCr alloys, hydrogen promotes internal oxidation of Cr also in NiCr alloys.

In spite of this similarity in mechanism, the gas composition dependence of borderline NiCr alloys substantially differs from that of corresponding FeCr alloys, the most obvious difference being that the high oxidation rates observed for Fe-10Cr and Fe-20Cr in Ar-H<sub>2</sub>O<sup>46</sup> are not found for Ni-based alloys with the same Cr content (Figure 29). The reason is that the growth rate of NiO strongly decreases with decreasing  $p_{O_2}$ , with the result that in Ar-H<sub>2</sub>O the NiO growth rate is extremely small,<sup>32</sup> that is, in fact similar to that of chromia. Even if the Cr content was so low that a protective chromia scale could not form, the overall oxidation rate would still be quite low because of the very slow growth rate of NiO in Ar-H<sub>2</sub>O (Figure 28), and, obviously, in Ar-H<sub>2</sub>-H<sub>2</sub>O the NiO will not form at all.

Fe oxide exhibits quite high growth rates in Ar-H<sub>2</sub>O mixtures,<sup>14,16,36</sup> and for an Fe-10Cr alloy in Ar-H<sub>2</sub>O the enhanced internal oxidation of Cr will, thus, in contrary to Ni-10Cr, result in formation of rapidly growing Fe-rich oxide scales. The behavior of borderline FeCr alloys in Ar-H<sub>2</sub>O-H<sub>2</sub> mixtures strongly depends on the exact gas composition

because the equilibrium oxygen partial pressure in a gas with a H<sub>2</sub>O/H<sub>2</sub> ratio of 1 is very near to the dissociation pressure of Fe oxide (Figure 2).

#### 1.17.4.4 Oxidation of Ferritic and Austenitic Steels in Steam

##### 1.17.4.4.1 General remarks

A technologically important example in which 'borderline' FeCr- and FeNiCr-based alloys are subjected to steam at relatively high temperatures is encountered in many power generation systems. In conventional power plants, steam-carrying components are commonly designed using low-Cr (e.g., 2¼% Cr) steels. The behavior of this type of materials at steam temperatures up to  $\approx 530$  °C has frequently been described<sup>86,87</sup> and will not extensively be treated here. Increasing the steam temperature to 600 °C and even higher for obtaining higher energy conversion efficiencies requires construction materials that possess a higher creep strength than that of the low-Cr steels. This led to introduction of martensitic steels with Cr contents of 9–10% for tubing in heat exchanging components (e.g., T91, T92) as well as for various components in steam turbines.<sup>88</sup> Depending on the actual application, steels with higher Cr contents (e.g., 12% Cr in X20CrMoV12 1 or HCM 12) are considered (Table 1); however, these generally possess a lower creep strength than the 9% Cr steels.<sup>89</sup> Based on the results in the previous section, martensitic 9–12% Cr steels may, from the viewpoint of oxidation resistance, be considered as

**Figure 29** Weight change of Ni-10Cr and Fe-10Cr (a), as well as Ni-20Cr and Fe-20Cr (b) after 72 h isothermal oxidation at 1050 °C in different test environments. Dotted/dashed lines do not present a real  $pO_2$  dependence of the oxidation rate; they are just inserted for clearer visibility of the data points.

**Table 1** Typical examples of ferritic, martensitic, and austenitic steels as well as Ni-based alloys presently considered as construction materials for steam-carrying components in fossil fuel-fired power plants

Report Forschungszentrum Jülich, Jül-3883, 2001; ISSN 0944-2952.

'borderline' alloys. This is confirmed by the results in [Figure 30](#), which shows the weight change data of the 9% Cr steel P92 during exposure at 650 °C in air and in Ar-50% H<sub>2</sub>O.

#### 1.17.4.4.2 Steam oxidation mechanisms of 9–12% Cr steels

During exposure in (simulated) steam in the temperature range 550–650 °C, all ferritic 9–12% Cr steels tend to exhibit an incubation period in which the oxidation rates are very low ([Figure 31](#)). This incubation period can range from minutes to several hundreds of hours and it increases with increasing amount of protective scale-forming elements (e.g., Cr, Si) and the extent of cold work. In this oxidation stage, oxide layers of the type (Fe,Cr)<sub>2</sub>O<sub>3</sub> and/or Cr-rich (Fe,Cr)<sub>3</sub>O<sub>4</sub> covered by a hematite layer are formed.<sup>4,19,90</sup>

After longer exposure times, breakdown of this protective scale occurs, which is accompanied by formation of rapidly growing magnetite and a zone with internal Cr<sub>2</sub>O<sub>3</sub> precipitates ([Figure 31](#)).<sup>46</sup> At temperatures above approximately 580 °C, wüstite may be present near the scale–steel interface.<sup>16,84,87</sup> The inner and outer layers are separated by a gap,

probably caused by vacancy condensation resulting from the rapid outward growth of the outer magnetite layer ([Figure 31](#)). Further growth of the scale depends to a large extent on transport processes within this gap, likely by the so-called H<sub>2</sub>/H<sub>2</sub>O bridges (see [Section 1.17.3.3](#)). This explains why there is a relative movement of the 'transient gap' towards the magnetite layer in the outer part of the scale during prolonged exposure. As the overall scale thickness increases, the Fe activity at the scale–gas interface gradually decreases because of the increasingly difficult transport of Fe cations to the oxide surface as a result of the presence of the in-scale gap ([Figures 31 and 32](#)). This decrease in Fe activity in the outer scale eventually results in formation of hematite, that is, the oxide in equilibrium with the gas atmosphere ([Figure 32](#)), on top of the scale. The formation of hematite starts at the grain boundaries of the magnetite layer ([Figure 32\(b\)](#)). Additionally, molecular gas transport occurs through the outer scale.<sup>83</sup>

For a 10% Cr steel at 650 °C, time  $t_1$  in [Figure 31](#) is ~10–15 min and  $t_5$  ~5 h<sup>91</sup>. Exact times, however, differ with the water vapor content, exact steel composition and surface deformation, for example,

**Figure 31** Proposed mechanism for the oxide scale formation on ferritic 10% Cr steel in Ar-H<sub>2</sub>O mixtures. Times  $t_1, t_2, t_3, t_4, t_5$  represent subsequent time steps during the oxidation process. Reproduced from Quadakkers, W. J.; Ennis, P. J.; Žurek, J.; Michalik, M. *Mater. High Temp.* **2004**, 22(1/2), 37–47.

introduced by grinding or cold work. The depth of the internal oxidation zone tends to decrease with increasing temperature, as will be more extensively discussed later.

The change from protective to non-protective oxidation ( $t_1 \rightarrow t_2$  in Figure 31) can be explained by the enhanced oxygen transport in voids by H<sub>2</sub>/H<sub>2</sub>O as proposed by Fujii and Meussner.<sup>92</sup> During exposure in oxygen or air, and during the incubation period in wet gas ( $t_1$ , Figure 31), voids may be formed at the interface between steel and the protective Cr-rich oxide as result of vacancy condensation. In the case of Cr<sub>2</sub>O<sub>3</sub>,  $p_{O_2}$  at the scale–alloy interface at 650 °C is  $\sim 10^{-34}$  atm and the flux of oxygen ( $\mathcal{J}_{O_2}$ ) across a void can be calculated using the Hertz–Langmuir equation:<sup>93</sup>

$$\mathcal{J}_{O_2} = \frac{p}{(2\pi MRT)^{0.5}} \quad [17]$$

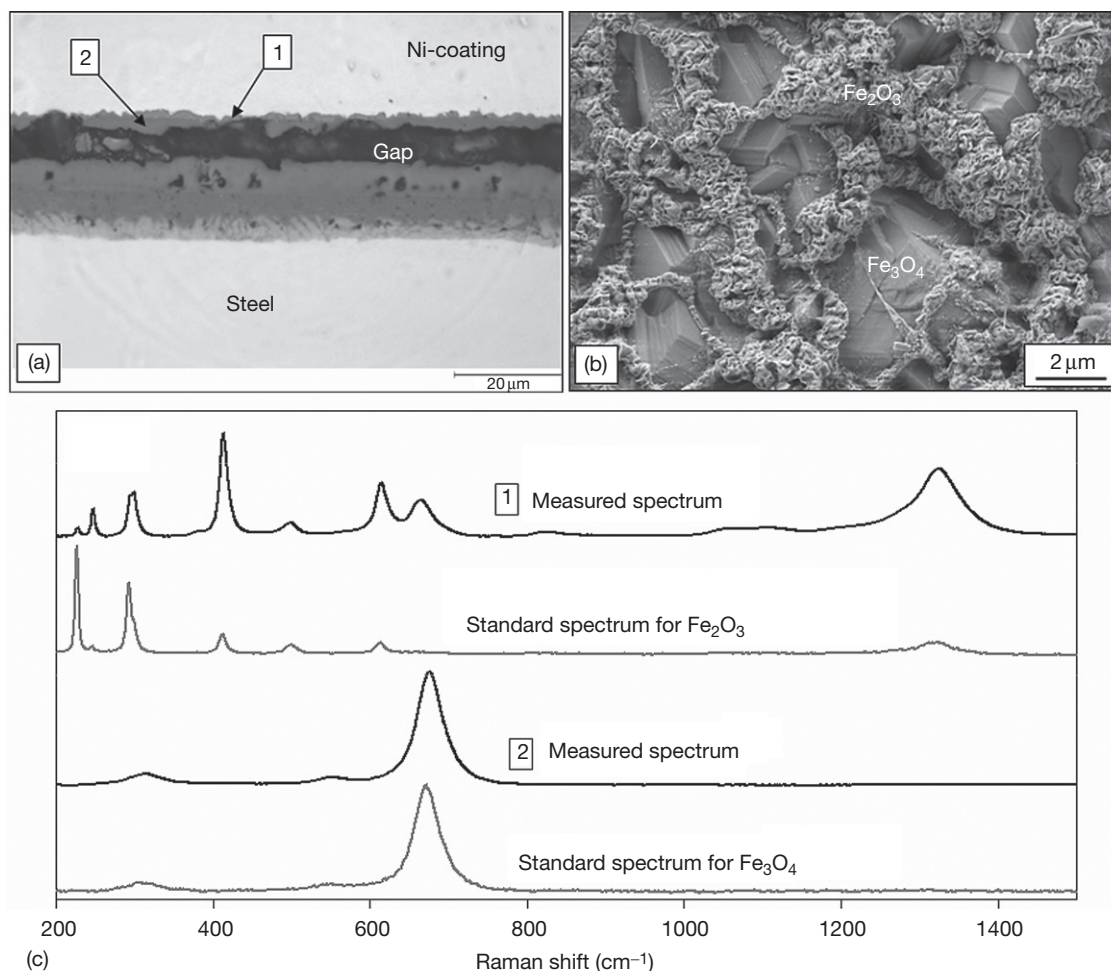

where  $p$  is the vapor pressure and  $M$  the mass of the gas molecules. The flux is found to be extremely low (in the range  $8 \times 10^{-34}$  g cm<sup>-2</sup> s<sup>-1</sup>), thus giving Cr sufficient time to diffuse from the bulk alloy towards the inner surface of the void, which can, therefore, heal by again forming a Cr-rich scale. Such a healing process could be illustrated by the TEM cross sections of an oxide scale on a 9% Cr steel after air

exposure at 650 °C.<sup>16</sup> If, however, H<sub>2</sub>O(g) is present in the void, its partial pressure will be determined by the equilibrium:

Calculating the equilibrium gas composition at a total pressure of 1 atm, assuming the gas Ar–50% H<sub>2</sub>O to be in equilibrium with the dissociation pressure of the oxide ( $10^{-34}$  atm), reveals for  $p_{H_2O}$  a value of  $10^{-6}$  atm. Putting this value in the Langmuir equation, it is found that an oxygen flux of  $5 \times 10^{-6}$  g cm<sup>-2</sup> s<sup>-1</sup> can be sustained. This is substantially larger than the actually observed oxidation rate in the wet gas. Thus, oxygen transport via the H<sub>2</sub>/H<sub>2</sub>O bridges<sup>36</sup> in voids within the scale can in principle explain the breakdown of the protective Cr-rich oxide and can account for the high oxidation rates in Ar–H<sub>2</sub>O.

However, based on the considerations in the previous sections, the change from protective to non-protective oxidation will likely be triggered by enhanced internal oxidation of Cr due to hydrogen dissolution in the alloy. Water vapor and hydrogen can be transported through the oxide layer, for example, via microcracks formed as a result of growth stresses.<sup>66</sup> Nakagawa *et al.*<sup>94</sup> considered the case where different oxidation processes were occurring on two sides of

**Figure 32** Metallographic cross section (a) and SEM picture (b) of oxide surface of 10Cr-1Mo-1W (low Si) steel after 5 h oxidation in Ar-4% H<sub>2</sub>O at 650°C. Point 1 and 2 in (a) relate to Raman analyses in (c). Reproduced from Zurek, J.; Michalik, M.; Schmitz, F.; Kern, T. U.; Singheiser, L.; Quadakkers, W. J. *Oxid. Met.* **2005**, 63(5/6), 401–422.

ferritic steels when used as a boiler tube material for power stations. It was proposed that hydrogen generated on one side of the tube wall diffuses to the side with the higher  $p_{O_2}$  and deteriorates the protective properties of the air-formed chromia base scale. In many cases cited above, hydrogen diffusion into the metal was observed, a clear sign of direct reaction of the water vapor in the oxidation process.

#### 1.17.4.4.3 Void and gap formation

The oxide scales after oxidation of 9–10% Cr steels in water vapor contain nearly always a substantial amount of pores and/or microvoids (Figure 33), finally resulting in the formation of gaps that may promote spallation of the scales during thermal cycling. The main reason for void formation in the oxide scale given in the

literature is vacancy condensation as a result of the fast outward migration of metal ions through the scale.<sup>6,49</sup>

During long-term exposure, void formation seems to occur at different locations in the scale. First voids ('transient gap') start to form already after very short oxidation times as shown in Figure 31. If the isothermal exposure is continued, the 'transient' gap may heal by growth of the inner oxide scale as water vapor molecules gain access through the outer layer, and the gap may eventually completely close which results in a more or less compact scale. Transport of Fe cations to the surface then becomes again possible and thus the Fe activity at the oxide surface increases. At a sufficiently large flux of Fe cations, the outer hematite transforms into magnetite, and after longer times (at 650°C, for example, a few hundred hours)

**Figure 33** (a) Isothermal oxidation of a 10Cr–Mo–W–Si steel at 625 °C in Ar–7% H<sub>2</sub>O showing buckling of oxide separation at hematite–magnetite interface, (b) oxidation of 10Cr–Mo–W–Si steel at 600 °C in Ar–50% H<sub>2</sub>O (intermediate cooling every 250 h) showing formation of compact oxide layer. No evidence of spalling was found up to the total exposure time of 1000 h. Reproduced from Quadakkers, W. J.; Ennis, P. J.; Žurek, J.; Michalik, M. *Mater. High Temp.* **2004**, 22(1/2), 37–47.

the scale appearance is then similar to that shown in [Figure 33\(b\)](#).

If a thermal cycle is introduced in the early stages of the oxidation process, that is, before healing of the ‘transient gap,’ scale spallation occurs. Further exposure then results in growth of the freely exposed magnetite layer eventually leading to a scale morphology similar to that shown in [Figure 33\(b\)](#). The question of whether spallation or healing of the outer layer above the gap occurs thus depends on the time at which, for a given temperature, the thermal cycle is introduced. This could be shown for a 10Cr–Mo–W–Si steel after exposures at 600 and 625 °C in Ar–H<sub>2</sub>O.<sup>91</sup> If the specimen was cooled after 70 h exposure, spallation of the top layer occurred because of the presence of the in-scale gap. If the first temperature cycle was introduced after 250 h, sufficient time was available for healing of the gap and thus excellent oxide adherence was found even after extended exposure for several thousand hours.

As long as the scale contains an outer hematite layer, local buckling by a separation at the magnetite–hematite interface is sometimes observed ([Figure 33\(a\)](#)). This might be related to a mechanism which is similar to that frequently described for oxide films on, for example, pure chromium,<sup>39</sup> that is, lateral growth of the scale due to in-scale oxide formation at scale grain boundaries. The cation and anion diffusion in the Fe<sub>2</sub>O<sub>3</sub> lattice are known to be much smaller than in magnetite and wüstite. Therefore, scale growth is likely to occur to a large extent via and at the oxide grain boundaries, and thus in-scale growth can occur by reaction of inwardly and outwardly moving species.

The time required for complete healing of the ‘transient’ gap tends to increase with decreasing temperature. After 550 °C exposure, remnants of the gap within the magnetite can sometimes be found up to quite long exposure times of more than 1000 h ([Figure 34\(a\)](#)), whereas after the same exposure time at higher temperatures only a dense magnetite layer, sometimes with isolated voids in the outer scale, is found ([Figure 34\(b\)](#)).

#### 1.17.4.4.4 Long-term behavior

The long-term behavior of the various types of commercially available martensitic Cr steels in steam in the temperature range 550–650 °C can be rationalized on the basis of a graph similar to that shown in [Figure 13](#). The borderline between the various oxidation regimes is substantially affected by alloying additions, as seen by the data in [Figure 35](#), with the result that a large variation in oxidation rates for group II alloys with the same Cr contents may be observed. As will be shown later, the exact location of the borderline between the various types of oxide scales depends on temperature. Taking these restrictions into account, it can be said that ferritic steels with a Cr content of less than approximately 8% (group I) exhibit at 600–650 °C high oxidation rates and the main oxide phases present in the surface scales are magnetite and (Fe,Cr) spinel. Steels of group III exhibit very low oxidation rates and the oxide scales mainly consist of Cr<sub>2</sub>O<sub>3</sub> and (Cr,Fe)<sub>2</sub>O<sub>3</sub>. The steels of group II are ‘intermediate cases’ because the oxidation rates and scale morphologies may substantially differ as a function of time, temperature, minor alloying additions, and surface treatment.

There is general consensus that steam-side oxidation of ferritic and martensitic boiler tubes occurs at a rate given by:

$$x = K' t^n \quad [19]$$

where  $x$  is the oxide scale thickness,  $t$  is the exposure time,  $n$  is the rate exponent, and  $K'$  is the proportionality coefficient, which is a function of temperature, alloy composition, oxygen partial pressure, stress level, and radius of curvature of the tubing. For tubing of ferritic/martensitic steels from groups I and II,  $n$  has been found to vary from 1/2 to 1/3, and is believed to be a function of time and temperature.<sup>88</sup>

During exposure of the ferritic steels of group I or II (Figure 35) for longer times of, for example, 1000 h

in the temperature range 600–650 °C, the outer magnetite layer is mostly compact and no hematite can be found (Figure 36). The magnetite frequently contains cracks perpendicular to the oxide surface, which are caused by tensile cracking during cooling due to the high thermal expansion coefficient of the magnetite.<sup>95</sup>

Upon prolonged exposure, the scales start to develop more and more microvoidage. This first occurs in the inner scale (Figure 36). Here the largest extent of void formation seems to develop at the interface between the internal oxidation zone, if present, and the inner oxide layer (Figure 36). The eventual pore morphology and distribution in the inner scale depend on the way in which the vacancies within the scale and/or at the scale–alloy interface

**Figure 34** Effect of temperature on morphology and void/gap formation of scale on 10Cr–1Mo–1W (low Si) steel during exposure in Ar–50% H<sub>2</sub>O for 1000 h: (left) 550 °C; (right) 600 °C. **Figure 35** Weight change of various ferritic and martensitic steels after 250 h oxidation in Ar–50% H<sub>2</sub>O at 600 °C, derived from data in Ehlers and Quadackers.<sup>4</sup> Designations ‘Group I–III’ are explained in the text.

**Figure 36** Oxide scale formed on 10Cr-1Mo-1W steel during exposure for 1000 h in Ar-50% H<sub>2</sub>O at 650 °C: (a) overview; (b) higher magnification of scale-steel interface; (c) steel microstructure. Reproduced from Ehlers, R. J.; Ennis, P. J.; Singheiser, L.; Quadackers, W. J.; Link, T. In EFC Workshop 2001; Schütze, M.; Quadackers, W. J., Nicholls, J. R., Eds.; The European Federation of Corrosion Publications, 2001; Vol. 34, Paper 12, pp 178-193.

coalesce to voids. **Figure 36** shows a clear difference in pore morphology in the outer pure Fe<sub>3</sub>O<sub>4</sub> layer and in the inner two-phase layer consisting of Fe<sub>3</sub>O<sub>4</sub> + (Fe,Cr,Mn)<sub>3</sub>O<sub>4</sub> and in the internal oxidation zone adjacent to the alloy. Numerous tiny voids are present in the inner two-phase layer (**Figure 36**) which seem to be correlated with the (Fe,Cr,Mn)<sub>3</sub>O<sub>4</sub> bands embedded in the Fe<sub>3</sub>O<sub>4</sub> matrix.<sup>4</sup> Apparently, the interfaces between these bands and the magnetite act as nucleation sites for the voids. For a given alloy, the morphology and distribution of the ‘bands’ depend on temperature, as will be illustrated later.

This type of void formation, as well as the morphologies of the inner spinel layers and the zone of internal oxidation, is affected by the underlying steel microstructure (**Figure 37**), including carbides preferentially formed at steel grain boundaries and/or martensitic laths.<sup>96</sup> **Figure 38** compares the scale cross sections of a 10Cr-Mo-W steel with that of a Fe-9% Cr model alloy manufactured from

high-purity elements after 1000 h exposure in Ar-50% H<sub>2</sub>O. Although the thicknesses of the scales on the two materials do not substantially differ, the void and crack morphologies exhibit tremendous differences. The most striking difference is the large gap occurring in the case of the model alloy near the alloy-steel interface, but not in case of the commercial steel. This is likely related to differences in the mechanisms of vacancy condensation, due to the absence of carbide precipitates in the model alloy. This results in a concentration of the voidage at the scale-steel interface, whereas in case of the commercial steel the voids at first tend to be evenly distributed in the whole inner layer.

During long exposure of the commercial steels of group II, voidage also starts to occur in the outer magnetite layer (**Figure 36**). These voids can be unevenly distributed or they can coalesce to a gap at the interface between the inner and outer layers (**Figure 39(a)**). Indications have been found that the latter is caused by limitations of the cation transport in the inner scale. Here three possible reasons may be mentioned<sup>97</sup>:

1. The continuing formation of voids in the inner scale decreases the transport area available for cation diffusion.
2. The two-phase mixture of FeCr spinel and magnetite in the inner scale changes, near the interface between outer and inner scale, to a single-phase layer. Magnetite, which acts as ‘rapid diffusion path’ for Fe cations, vanishes with the result that the transport of Fe cations from the inner to the outer scale decreases.
3. The formation of a protective, Cr-rich spinel layer at the oxide-alloy interface.

The limitation of cation transport has the result that the growth rate of the outer magnetite in the existing oxygen activity gradient can no longer be sustained. Consequently, inwardly moving vacancies in the magnetite tend to condense at the interface between the inner and the outer layer resulting in void and gap formation (**Figure 39(a)**).

The formation of a Cr-rich layer at the oxide-alloy interface (No. 3 above) preferentially occurs at higher temperatures (at and above 600 °C) because then diffusion of Cr in the alloy and/or the rate of spinel formation are sufficiently fast. It is also favored by increasing the amounts of protective scale-forming elements (Cr, Si), and, therefore, the tendency for extensive void formation in the outer magnetite layer and/or at the interface between inner and outer scale

**Figure 37** Cross-sections of oxide scales on specimens of 9% Cr steel P92 after oxidation for 1250 h at 650 °C in Ar–50% H<sub>2</sub>O. Prior to exposure the specimens were heat-treated so that they had a martensitic (a) or ferritic (b) microstructure. Reproduced from Ehlers, R. J.; Ennis, P. J.; Singheiser, L.; Quadakkers, W. J.; Link, T. In EFC Workshop 2001; Schütze, M.; Quadakkers, W. J., Nicholls, J. R., Eds.; The European Federation of Corrosion Publications, 2001; Vol. 34, Paper 12, pp 178–193.

**Figure 38** Metallographic cross sections of oxide scales on (a) commercial 10Cr–Mo–W steel and (b) Fe–9% Cr model alloy (manufactured from high-purity materials) after 1000 h isothermal exposure in Ar–50% H<sub>2</sub>O at 625 °C, showing differences in void/gap formation in the scale. Reproduced from Quadakkers, W. J.; Ennis, P. J.; Żurek, J.; Michalik, M. *Mater. High Temp.* **2004**, 22(1/2), 37–47.

**Figure 39** Different types of scale spallation during oxidation on 10Cr–1Mo–1W low Si steel after long-term exposure in Ar–50% H<sub>2</sub>O at (a) 625 °C and (b) 650 °C.

will in principle be larger for steels of group II in **Figure 13** than for lower Cr steels (group I).

As explained in **Section 1.17.4.4.2**, extensive void/gap formation will eventually result in the formation of hematite on top of the outer magnetite layer. Macroscopic observation of hematite is thus frequently a strong indication for the formation of a heavily voided/cracked magnetite layer, which is expected to be prone to spallation. Nishimura *et al.*<sup>98</sup> described a similar mechanism for the hematite formation and claimed that the transformation of magnetite into hematite plays a role in oxide spalling. An interesting feature is that the outer surface of the hematite is in some cases flat; in other cases it exhibits a whisker type morphology, possibly related to a mechanism described in **Section 1.17.3.1** for whisker formation on chromia scales. The reasons for these differences in morphology of the hematite are, as far as known to the authors, not fully clarified.

On the basis of the described mechanisms of void/gap formation, it can generally be said that the crack initiation/propagation modes occurring can result in three different types of scale spallation: that is, spalling occurring in the outer magnetite layer (**Figure 39(a)**); near the interface between the oxide and the alloy or the internal oxidation zone (**Figure 39(b)**); or at the interface between inner and outer scale (**Figure 39(a)**). The latter mode preferentially occurs in case of group II alloys with higher Cr (and Si) contents and is similar to that frequently found for austenitic steels (see **Section 1.17.4.4.6**).

#### 1.17.4.4.5 Temperature dependence of oxidation during long-term exposure

Watanabe *et al.*<sup>99</sup> investigated the oxidation behavior of various steels in steam in an autoclave in the range 560–700 °C. Low alloy steels (group I) showed the same activation energy ( $Q$ ) for the oxidation rate constant, that is, 350–400 kJ mol<sup>-1</sup>, over the entire temperature range (**Figure 40**). On the other hand, the 9% Cr and 12% Cr steels (group II) showed a bilinear behavior. Below 600 °C they had the same  $Q$  but exhibited much lower values in the range 600–700 °C; the higher the Cr content, the lower the  $Q$  values. HCM12A had a  $Q$  value of 40 kJ mol<sup>-1</sup>.

The data show that the oxidation behavior of steels with Cr concentrations between 2 and 8% in superheated steam at temperatures below 600 °C is virtually independent of the Cr content.<sup>100</sup> The difference between 9% Cr steels and 12% Cr steels is also small at 600 °C but becomes marked at 650 °C.

**Figure 40** Arrhenius-type plots of oxidation rate constant  $K_p$  measured at 10 MPa. Reproduced from Yi, Y. S.; Watanabe, Y.; Kondo, T.; Kimura, H.; Sato, M. *J. Pressure Vessel Technol.* **2001**, 123, 391–397.

A similar difference in temperature dependence of various steel types was found by Ehlers *et al.*<sup>4</sup> after exposure in Ar–50% H<sub>2</sub>O at 1 bar pressure. Also, the data from Husemann,<sup>101</sup> derived from service exposed tubes, show that at low temperatures (~550 °C) the oxidation rates of the 9% Cr steels are not substantially lower than those of the low alloy steels (**Figure 41**). These data also show that large differences in oxidation rates may occur between different batches of one steel, here shown for X20 ‘low Cr’ and ‘high Cr.’ This was also found by other authors during laboratory tests of 10.5% Cr and 11.3% Cr batches of this steel type (**Figure 41(c)**). The results in Refs. 4 and 101 indicate that at 550 °C a clear difference exists between low alloy steels and 12% Cr steel. This contradicts the results of Yi *et al.*<sup>100</sup>

The differences in temperature dependence of the oxidation rates for various steel types (**Figure 40**) are mainly related to the enhanced incorporation of chromium and other protective scale-forming elements into the scale upon temperature increase. The tendency to form surface scales which are richer in Cr upon increasing the temperature from, say, 550–650 °C is in some steels even more pronounced if the temperature is even further increased. This then has as result that the oxidation rate of, for example, P91 at 700 °C is, at least during short-term oxidation, smaller than at 600 °C.<sup>102</sup>

**Figure 41** (a, b) Oxidation rates for various steels derived from literature data and service-exposed tubes. The rate constant  $K$  here refers to the material loss  $x$  in mm defined as  $x^2 = Kt$  whereby  $t$  is the time in hours.<sup>101</sup> (c) Weight changes for various steels after laboratory tests of 250 h in Ar-50%  $\text{H}_2\text{O}$ .<sup>4</sup> Designation 'X20' relates to X20CrMoV12-1 (see Table 1).

Depending on the exact steel composition, a decreasing oxidation rate with increasing temperature can already occur at lower temperatures. **Figure 42** shows the mass change data after 1000 h exposure of different steels at different temperatures in Ar-50% H<sub>2</sub>O. Samples of 1Cr-Mo-V and 10Cr-Mo-W steels clearly exhibit increasing oxidation rates with increasing temperature (**Figure 42**). However, the 12% Cr steel exhibits lower oxidation rates at 625 °C than at 550 °C, whereas the Co-containing 11% Cr steel shows a quite complex temperature dependence (**Figure 42**). After 1000 h exposure at

625 °C, the weight changes are clearly lower than those observed after the 550 °C exposure, whereas at 600 °C the value is only slightly smaller than that at 550 °C. It is important to note that the high value at 600 °C was already reached after 250 h; in other words, the oxidation rate between 250 and 1000 h is as small as that observed at 625 °C.

**Figure 43** shows the oxide scales formed on the Co-containing steel after 1000 h of exposure at 550 and 600 °C. In agreement with the mass change data in **Figure 42**, the thicknesses of the scales formed at 550 and 600 °C are quite similar. However, the scale

**Figure 42** Weight changes of four different ferritic steels after exposure for 1000 h in Ar-50% H<sub>2</sub>O showing different types of temperature dependence of the oxidation rates. Also inserted is the weight change of the 10Cr-6Co-1Mo steel after 250 h, showing that between 250 and 1000 h hardly any weight gain occurred. Reproduced from Žurek, J.; Wessel, E.; Niewolak, L.; Schmitz, F.; Kern, T. U.; Singheiser, L.; Quadakkers, W. J. *Corros. Sci.* **2004**, 46(9), 2301–2317.

**Figure 43** Backscattered electron images and Cr distribution in scales formed on 10Cr-Co-Mo steel after 1000 h exposure in Ar-50% H<sub>2</sub>O at 550 and 600 °C showing the temperature dependence of Cr distribution in the inner scale. Reproduced from Žurek, J.; Wessel, E.; Niewolak, L.; Schmitz, F.; Kern, T. U.; Singheiser, L.; Quadakkers, W. J. *Corros. Sci.* **2004**, 46(9), 2301–2317.

morphologies show substantial differences. At 550 °C, the inner part of the scale exhibits a wide zone of internal oxide precipitates which are embedded in a Co-rich alloy matrix. After exposure at 600 °C, the internal oxidation zone is absent.

At 550 °C, chromium diffusion in the alloy and in the oxide is so slow that Cr can be considered as being virtually immobile. It becomes preferentially incorporated in the inner part of the scale as a result of oxidation of the Cr-rich carbides at the steel grain boundaries and/or martensite laths prevailing in the alloy.<sup>97</sup> The Cr-rich internal oxides become subsequently embedded in the scale by the inwardly moving oxidation front.<sup>96</sup> The Cr-rich bands in the inner scale thus exhibit a sort of ‘fingerprint’ of the typical microstructure in this type of steel (Figures 36(b) and 36(c)).

On the basis of the initial rapid mass change (Figure 42), the scale formation mechanism at 600 °C is more similar to that at 550 °C than that at 625 °C. However, after longer times the oxidation rate resembles that found at the higher temperatures, which means that somewhere in the scale a protective Cr-rich oxide becomes stabilized after about 250 h of exposure. The element mapping in Figure 43 shows that the overall Cr enrichment in the inner part of the scale is not very pronounced, but a strong enrichment

is visible in a narrow band near the scale–alloy interface. Beneath this, a Cr depletion in the alloy as a result of the selective oxidation of Cr is clearly visible. The enhanced diffusion and the associated increase in the selective oxidation of Cr become more pronounced if the temperature is increased to 625 °C. The Cr-rich oxide then becomes stabilized already in the very early stages of oxidation, resulting in an extremely slow oxidation rate during the whole 1000 h of exposure (Figure 42).

Qualitatively, these features in respect to the adverse temperature dependence of the oxidation behavior can also be observed in the case of the 12% Cr steel (Figure 42), in agreement with earlier findings of Haarmann *et al.*<sup>103</sup> for this type of steels. At 550 °C, the Cr-enriched regions almost exclusively consist of oxides initially formed on grain boundaries and martensite laths, thus expressing the original microstructure in the steel. After exposure at 625 °C, the alloy exhibits Cr-rich stringers in the inner oxide layer, arranged parallel to the initial steel surface, indicating more rapid Cr diffusion from the bulk alloy in the direction of the scale.<sup>104</sup> This preferential oxidation of Cr results in a Cr depletion beneath the Cr-rich spinel layer in the alloy. After continued Cr depletion, the growth of the Cr-rich spinel can eventually no longer be

**Figure 44** Backscattered electron images and Cr distributions in inner scale formed on 12Cr–Mo–V steel after 1000 h exposure at 550 and 625 °C showing temperature dependence of Cr incorporation and distribution in inner scale. Reproduced from Z'urek, J.; Wessel, E.; Niewolak, L.; Schmitz, F.; Kern, T. U.; Singheiser, L.; Quadakkers, W. J. *Corros. Sci.* **2004**, 46(9), 2301–2317.

**Figure 45** Weight changes of binary Fe–Cr model alloys after 250 h exposure in Ar–50% H<sub>2</sub>O in the temperature range 550–650 °C. Adapted from Nieto-Hierro, L.; Quadakkers, W. J. Unpublished results, Forschungszentrum Jülich, FRG, 2006.

**Figure 46** Weight changes of Fe–Cr model alloys with various additions of minor elements, after 250 h exposure in Ar–50% H<sub>2</sub>O in the temperature range 550–650 °C. Derived from Nieto-Hierro and Quadakkers.<sup>105</sup>

sustained, and as a result Fe-rich oxides are subsequently formed. Repetition of this process leads to the microstructure in the inner part of the scale shown in Figure 44.

The adverse temperature dependence (Figure 42) can thus be expected in steels that exhibit a higher tendency to form protective Cr-rich scales (group II, Figure 13), that is, it increases with increasing amounts of elements (Cr, Si, etc.) that participate in the formation of protective scales.

The adverse temperature dependence, shown for two steels in Figure 42, in fact seems to contradict the results and considerations in Section 1.17.4.3.3 which showed that for binary FeCr alloys in the temperature range 800–1050 °C the tendency to form protective scales decreases with increasing temperature. The results obtained for high-purity Fe–Cr

model alloys in Figure 45 illustrate that this is also the case for steam oxidation in the temperature range 550–600 °C.<sup>105</sup> If a different temperature dependence is sometimes observed for the commercial ferritic steels, then apparently factors other than just temperature dependence of Cr and oxygen diffusion in the alloy affect protective scale formation. On the basis of studies with a number of ternary and quaternary model alloys, parameters that affect this process are alloying elements such as Si and Mn which participate in the oxidation process, C content in the alloy which apparently affects the Cr-distribution and activity, as well as enhanced dissolution of carbides with increasing temperature thereby ‘releasing’ Cr for diffusion. The results in Figure 46 confirm the significance of minor additions of Si and Mn for decreasing oxidation rates upon temperature increase.

**Figure 47** Backscattered electron images (left) and X-ray mappings of oxide scale formed on model alloy Fe-9Cr-4Co after 1000 h of exposure at 650 °C in Ar-50% H<sub>2</sub>O. Pictures on left side show an overview of oxide scale and higher magnification of scale-steel interface, respectively. Adapted from Nieto-Hierro, L.; Quadackers, W. J. Unpublished results, Forschungszentrum Jülich, FRG, 2006.

For Si-containing steels, the occurrence of the adverse temperature dependence was also found by other researchers,<sup>106,107</sup> and a detailed description concerning the effect of Si for disappearance of the internal oxidation zone and the resulting formation of barrier layers was given by Ueda *et al.*<sup>84</sup> Single additions of other common alloying elements such as W, Co, and Nb did not fundamentally alter the  $T$ -dependence of the oxidation rates.<sup>4,105</sup> However, Co contents of more than 4% appeared to substantially affect the oxidation behavior of the Fe-Cr model as illustrated in **Figure 46**.

An Fe-9% Cr-4% Co model alloy forms at 650 °C an inner and outer scale (**Figure 47**), as shown for other steels before. However, here, the selective oxidation of Cr, and subsequently Fe, leads in the inner part of the scale to an apparent enrichment of Co in the remaining metallic regions due to the high dissociation pressure of Co oxide (**Figure 47**). X-ray diffraction (XRD) revealed even the presence of pure cobalt near the interface between inner and outer scale.<sup>105</sup> This results in a microstructure in which the transport of Fe cations is strongly hampered. In this way, sufficiently large additions of Co (e.g., 4%) substantially decrease the Cr content required to form protective Cr-rich oxide scales (**Figure 46**); however, no adverse temperature dependence is found.

#### 1.17.4.4.6 Austenitic steels

Attempts to further increase the steam temperature in power generation systems frequently requires the

**Figure 48** Scale growth rate  $K_p$  of various austenitic steels versus reciprocal temperature during steam oxidation. Here  $K_p$  is defined as  $K_p = x^2/t$  with  $x$  the scale thickness and  $t$  the time. Reproduced from Muramatsu, K. In *Development of Ultrasupercritical Plant in Japan, Advanced Heat Resistant Steel for Power Generation*; Viswanathan, R., Nutting, J. W., Eds.; IOM Communications: London, UK, 1999; Book 708, pp 543–559.

highest temperature components to be designed using austenitic materials, sometimes from the viewpoint of mechanical properties and in other cases for obtaining improved steam oxidation resistance.

The various austenitic steels that are potentially suitable as construction materials for heat-exchanging components widely differ in composition, for example, in respect to Cr and Ni content (Table 1), and consequently steam oxidation resistance may substantially differ between various materials.

Depending on the composition, the commercially available austenitics may, in respect to steam oxidation resistance, be described as group II or group III alloys in Figure 13. Steels with Cr contents in the range 17–20% may be considered as group II alloys and thus show oxide scales that exhibit many features similar to those described for the high-Cr ferritics of group II. Muramatsu<sup>108</sup> found that the oxidation rates of the austenitic steels are characterized by a single

activation energy over the entire temperature range between 550 and 750 °C, whereas the activation energy  $Q$  decreases as Cr concentration increases (Figure 48).

Oxide scales formed on austenitic steels are sometimes more prone to spallation than those on ferritic or martensitic steels. Figure 49 shows the gross and net mass changes of an austenitic 25Ni–15Cr–Ti steel as a function of time during exposure in Ar–50% H<sub>2</sub>O in the temperature range 550–650 °C. As described for some of the high-Cr group II ferritics (Section 1.17.4.4.5), different from the materials studied by Muramatsu<sup>108</sup> this austenitic steel shows an ‘adverse temperature dependence’: the growth rate of the initially formed surface scale at 650 °C is

**Figure 49** Mass changes as function of time during oxidation in the temperature range 550–650 °C in Ar–50% H<sub>2</sub>O: (a) Typical examples showing differences in behavior of martensitic 9–10% Cr steels, austenitics and Ni-base alloy; (b) Temperature dependence for onset of scale spallation for austenitic steel 25Ni–15Cr–Ti. ‘Net’ and ‘gross’ weight changes correspond to specimen mass changes without and with spalled oxide, respectively.

smaller than that at 600 °C. The data illustrates that no clear correlation exists between the oxidation rate and the time for the onset of scale spallation. For example, at 600 °C, the first spallation occurs after 3000 h where the net mass change is  $\sim 5 \text{ mg cm}^{-2}$ , while at 650 °C spallation occurs after 5000 h, that is, when the mass change equals  $\sim 3.5 \text{ mg cm}^{-2}$ . At 550 °C, spallation starts to occur after 2000 h exposure, where the mass change exceeds  $\sim 1 \text{ mg cm}^{-2}$ . The onset of spallation can thus not easily be correlated with a critical thickness of the oxide scale.

The metallographic cross sections presented in **Figure 50** illustrate the typical scale morphologies on austenitic steels. Spallation generally occurs at the interface between the inner and the outer scale, that is, near the original metal surface. After the total outer scale has spalled, the scale regrowth is determined by transport processes in the thick inner scale and thus occurs at a rate similar to that prevailing just before the occurrence of spalling. Owing to the high Cr content, Fe diffusion in the inner scale is slow, and thus the regrown oxide exhibits features as described in the previous sections, which means that it mainly consists of hematite on top of a gap. The spalling rate is thus governed by an initial smaller weight loss, a slow scale re-growth and consequently a smaller weight loss during the following spalling steps. This is, for example, clearly illustrated by the 600 °C curve in **Figure 49**.

There are, however, a number of major differences in oxide scale formation between 17% and 20% Cr austenitic steels and most of the commercially available 9–12% Cr martensitic steels. The effect of carbide formation on martensite laths for the inner scale morphology does obviously not occur in the austenitic steels. Also, chromium diffusion in austenite is slower by approximately a factor 10 than in ferrite.<sup>104,109</sup> Therefore, the critical Cr content to

obtain protective chromia base scale formation will generally be higher for austenitic than for ferritic steels. In coarse-grained austenitics, the change from formation of Fe/Cr spinel to pure  $\text{Cr}_2\text{O}_3$  was reported to require a Cr content of 25% such as prevailing in HR3C.<sup>88</sup> Owing to the slow diffusion, Cr transport along grain boundaries in the alloy plays a more important role in austenitics for the overall scale formation than in case of ferritic steels. This has the result that the steam oxidation behavior can be strongly affected by the steel grain size or by ‘imperfections’ introduced by surface deformation (**Figure 51**). An interesting feature sometimes found in austenitic steels is that the depletion of Cr beneath a Cr-rich surface scale may differ from grain to grain (**Figure 52**).

Beneficial effects due to grain refining have been pursued as a proven method for improving oxidation resistance of austenitic steels. A typical example is TP347HFG, which has been applied widely in the grain-refined condition, and favorable service experience up to 50 000 h is available. Currently, the technique is being extended to other stainless steels such as SUPER304H. Sato *et al.*<sup>110</sup> have described substantial beneficial effects on oxidation resistance of austenitic stainless steels due to shot-blasting. This technique has been applied to conventional austenitic steels in Japan for more than 20 years. The effect of cold work pretreatment on the corrosion rate<sup>111</sup> is explained by the improved diffusivity of Cr in the defect structure, preferential oxidation, and formation of Cr-rich solid solution ( $\text{FeFe}_{2-x}\text{Cr}_x\text{O}_4$ ) spinel-type oxide scales.<sup>112</sup>

Another important feature is the role of Ni in the overall oxidation process. The thermodynamic driving force for oxidation of Ni in the steam environment is much smaller than that for Cr or Fe.

**Figure 50** Metallographic cross sections of 25Ni-15Cr-Ti after oxidation in Ar-50% H<sub>2</sub>O at 550 °C after 3000 h and 600 °C after 10 000 h.

Therefore, Ni is generally not present in the outer magnetite–hematite scale. As described for Co in Co-containing martensitic steels in [Section 1.17.4.4.5](#), Ni is frequently found in the inner scale where it sometimes prevails in metallic form ([Figure 53](#))

because in that area of the scale the oxygen partial pressure is apparently lower than the dissociation pressure of NiO or Ni/Fe/Cr spinel. The chromium and oxygen distribution clearly show that the steel initially formed a Cr-rich surface layer, remnants of

**Figure 51** Metallographic cross sections showing effect of surface treatment on oxide scale formation of austenitic steel TP347HFG during exposure in Ar–50% H<sub>2</sub>O for 1000 h at 625 °C. **Figure 53** Backscattered electron image and X-ray mappings of oxide scale on steel Super304H after exposure at 625 °C for 10 000 h in Ar–50% H<sub>2</sub>O. Adapted from Piron-Abellan, J.; Quadakkers, W. J. Unpublished results, Forschungszentrum Jülich, FRG, 2007.

which can be seen between the inner and outer layer. In the inner scale, Cr-rich oxide is present as continuous bands at the alloy grain boundaries and as internal oxides within the grains. Areas with Ni-rich alloy matrix prevail in the inner scale especially near the initial steel surface.

#### 1.17.4.4.7 Effect of pressure on steam oxidation

Data regarding the influence of pressure on steam oxidation behavior show a considerable amount of variation.<sup>113</sup> Otoguro *et al.*<sup>114</sup> measured the maximum scale thickness on four austenitic alloys (SUS347 HTB, 17/14CuMo, 20Cr/25Ni and 22Cr/35Ni) after exposure to steam for 500 h at 650 and 700 °C and pressures up to 35 MPa. On increasing the pressure at 650 °C, two of the alloys (SUS347 HTB, 17/14CuMo) investigated showed a decrease in scale growth rate of ~20%, one of the alloys (22Cr/35Ni) showed no influence of pressure on the scale thickness and one alloy (20Cr/25Ni) showed an increase in scale thickness by a factor of 4. The same trend in results was observed at 700 °C. Montgomery and Karlsson<sup>115</sup> have summarized the data on the influence of pressure on scale growth kinetics during exposure of martensitic steels to steam environments. The high-pressure data for HCM12 indicated a decrease in scale growth rate with increasing pressure, whereas the high-pressure data for P92

revealed either no effect of pressure or a change in the pressure effect with temperature depending on interpretation.

An apparent influence of steam pressure on the scale morphology is illustrated in [Figure 54](#) for a ferritic 12Cr–1Mo–V steel oxidized for 250 h at 650 °C. When exposed to Ar–50% H<sub>2</sub>O at ambient pressure, hematite was formed at the outer surface, whereas only magnetite was present after the high-pressure oxidation. However, the high-pressure exposure was carried out in an autoclave in stagnant gas, and the observed effect is probably due to a build-up of hydrogen in the sealed system. This leads to a decrease in oxygen partial pressure, thus inhibiting hematite formation, as explained in [Section 1.17.2.3](#). The build-up of H<sub>2</sub> may also have affected the high-pressure results of Yi *et al.*,<sup>100</sup> which were carried out in stagnant gas.

#### 1.17.4.5 Alumina-Forming Alloys and Coatings

##### 1.17.4.5.1 $\alpha$ -Alumina scales

There are conflicting reports about the behavior of alumina-forming alloys and coatings in water vapor-containing gases. In an extensive review of the effects of water vapor on the oxidation of metals,<sup>1</sup> it was concluded that water vapor had little effect on the oxidation behavior of alumina-forming alloys, although some evidence was cited that hydrogen defects were

**Figure 54** Surface scale morphology of 12Cr–1Mo–V steel after 250 h exposure at 650 °C: (a) flowing Ar–50% H<sub>2</sub>O at 1 bar total pressure; (b) static steam at 300 bar total pressure. Adapted from Ehlers, J.; Quadackers, W. J. Report Forschungszentrum Jülich, Jül-3883, 2001.

**Figure 55** In-lens SEM images of oxide scales formed on an FeCrAlY model alloy after 100 h isothermal oxidation in low- and high- $p_{\text{O}_2}$  gas at 1250 °C. Reproduced from Naumenko, D.; Quadackers, W. J. Unpublished results, Forschungszentrum Jülich, FRG, 2007.

present in Mg-doped alumina and that scale adhesion was reduced by water vapor. It should be noted that the mentioned studies mainly relate to wet air or wet oxygen rather than low- $p_{\text{O}_2}$  gases.

Kolb-Telieps *et al.*<sup>116</sup> showed the  $\alpha$ -alumina scale on an FeCrAlY alloy in the temperature range 1200–1300 °C to grow more slowly in Ar–H<sub>2</sub>–H<sub>2</sub>O mixtures than in Ar–O<sub>2</sub> or air (Figure 55). Kochubey *et al.*<sup>117</sup> found a  $p_{\text{O}_2}$  dependence of the sub-parabolic oxidation rates assuming oxygen grain boundary diffusion to be the dominating scale growth process whereby the oxide grains size increased in scale growth direction.<sup>118</sup> Also in a low- $p_{\text{O}_2}$  exhaust gas<sup>116</sup> and in H<sub>2</sub>/H<sub>2</sub>O-based shield gases,<sup>119</sup> the growth rate of  $\alpha$ -alumina on an Y-doped FeCrAl alloy was found to be smaller than that in air. In the low- $p_{\text{O}_2}$  exhaust gas, Naumenko *et al.*<sup>120</sup> found, however, the adherence of the scales to be worse than that of the scales formed in air or Ar–O<sub>2</sub>. Poorer scale adherence of alumina scales due to presence of water vapor therefore seems to be a feature which is independent of the  $p_{\text{O}_2}$  of the test gas. It was also observed by Janakiraman *et al.*<sup>121</sup> during oxidation of Ni-based superalloys and MCrAl coatings in wet air. Dieckmann<sup>35</sup> proposed hydrogen segregation at the oxide–metal interface to be a possible reason for

poor scale adherence. Kirchheim<sup>122–124</sup> actually observed hydrogen to segregate at metal–oxide interfaces during internal oxidation of Pd-based alloys. In recent studies, Smialek<sup>125</sup> attributed the poor alumina scale adherence in wet gases to hydrogen embrittlement of the scale–alloy interface.

Toscano *et al.*<sup>126</sup> studied the thermal cycling behavior of a thermal barrier coated (TBC) coated Ni-based alloy where the bond coat (BC) was a NiCoCrAlY alloy containing 10 mass% Al. The  $\alpha$ -alumina scale that formed during cyclic oxidation at the BC surface beneath the TBC appeared to grow faster in air than in Ar–H<sub>2</sub>–H<sub>2</sub>O. As a result, the life time of the TBC at 1100 °C, which was governed by spallation of the  $\alpha$ -alumina scale at the BC surface, was substantially longer in Ar–H<sub>2</sub>–H<sub>2</sub>O than in air.

This gas composition dependence was found only in case of optimized reactive element (RE) doped alloys or coatings which formed a scale that does not allow molecular gas transport. FeCrAl alloys that contained Zr (300 ppm) as a second RE in addition to Y developed in Ar–O<sub>2</sub> as well as in Ar–H<sub>2</sub>–H<sub>2</sub>O alumina scales, which exhibited substantial porosity. This was related to internal oxide particles of zirconia that became incorporated into the inwardly growing

$\alpha$ -alumina scale during long-term exposure.<sup>127</sup> Porosity appeared to develop at the interfaces between the alumina scale and the zirconia particles. Therefore the scale did not develop the ideal columnar, large-grained microstructure shown in Figure 55, and probably molecular transport participated in the scale growth process. This had the result that the  $p_{O_2}$  dependence of the oxidation rate was far less obvious than in case of the Zr-free alloy (Figure 56). At higher temperature (1300 °C) in low- $p_{O_2}$  gas, variations in oxide thickness over the specimen were found and locally the scale was even thicker than after Ar- $O_2$  oxidation (Figure 57). Indications were found that the Ar- $H_2$ - $H_2O$  exposure modified the internal oxidation of the Zr in a manner similar to that described for FeCr alloys in Section 1.17.4.3.2, and in this way the Ar- $H_2$ - $H_2O$  indirectly changed the alumina growth rate. The strong dependence of the  $\alpha$ -alumina growth rate on scale

morphology may be the reason for the fact that Ramnarayanan *et al.*<sup>128</sup> found in the oxidation of an FeCrAl-based oxide dispersion strengthened (ODS) alloy at 1000–1200 °C no clear effect of oxygen partial pressure on scale growth kinetics.

#### 1.17.4.5.2 Metastable alumina

Naumenko *et al.*<sup>129</sup> also studied the effect of gas composition on the oxidation of Y-doped FeCrAl alloys at lower temperatures. The authors found that the dependence of the oxidation behavior on gas composition in the temperature range 800–950 °C was completely different from that at temperatures well above 1000 °C. At the lower temperatures, the Ar- $H_2$ - $H_2O$  mixture tended to promote the formation of rapidly growing, metastable aluminum oxide phases (e.g.,  $\gamma$ ,  $\Theta$ ) compared to Ar- $O_2$

**Figure 56** Weight changes during isothermal oxidation of FeCrAlY alloy (Y content 500 ppm) without or with 300 ppm Zr in high and low- $p_{O_2}$  gas at 1200 and 1300 °C. Reproduced from Naumenko, D.; Quadackers, W. J. Unpublished results, Forschungszentrum Jülich, FRG, 2007.

**Figure 57** SEM images of oxide scales on FeCrAlY + Zr alloy (compare [Figure 56](#)) after 100 h oxidation at 1300 °C in various atmospheres.<sup>117</sup> Reproduced from Kochubey, V. Ph.D. Thesis, Bochum University, 2005.

**Figure 58** Oxide scales on Ti-46.5Al-4(Cr, Nb, Ta, B) alloy after 96 h oxidation at 800 °C in Ar-20% O<sub>2</sub> and Ar-4% H<sub>2</sub>-2% H<sub>2</sub>O. Reproduced from Niewolak, L. Unpublished results, Forschungszentrum Jülich, FRG, 2003.

exposure. This effect was also found by Götlind *et al.*<sup>130</sup> when comparing the behavior of a commercial FeCrAl alloy in O<sub>2</sub> with that in O<sub>2</sub>-H<sub>2</sub>O, thereby indicating that presence of water vapor promotes metastable alumina growth, independent of the oxygen partial pressure in the gas. In a recent study, Lodziana *et al.*<sup>131</sup> demonstrated that strongly bonded hydroxide groups form on  $\Theta$ -Al<sub>2</sub>O<sub>3</sub> in the presence of water vapor. It was suggested that  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>, when formed on FeCrAl alloys at 900 °C, can generate a strongly bonded surface hydroxide similar to  $\Theta$ -Al<sub>2</sub>O<sub>3</sub>. This is supported by the observation that  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> powders can absorb significant amounts of water vapor (~3% by weight) at 900 °C.<sup>132</sup>

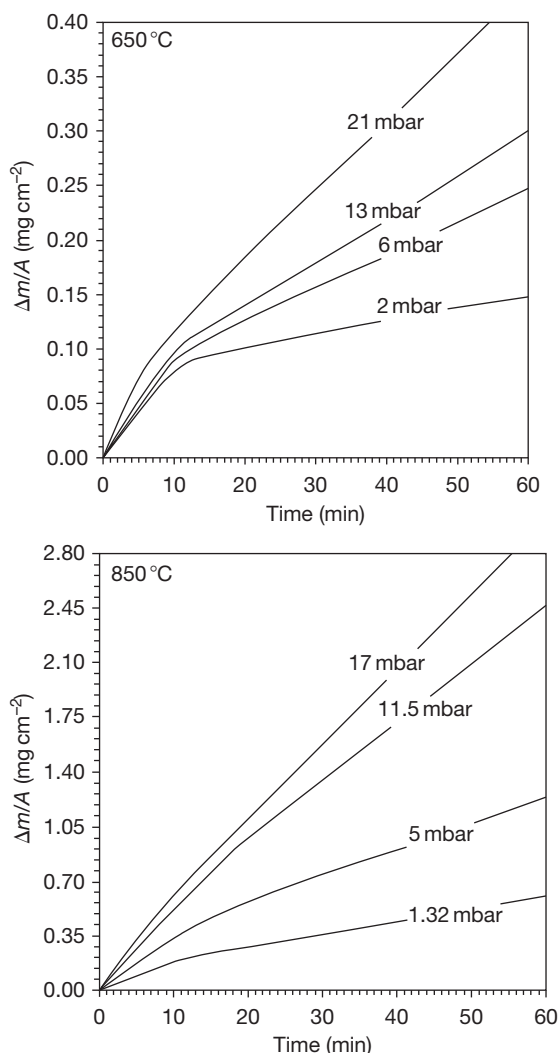

#### 1.17.4.5.3 Borderline alumina forming alloys

In earlier studies, Boggs<sup>133</sup> showed that the oxidation rate of Fe-5% Al was significantly increased at 800 °C when about 3% water vapor was present either alone or with oxygen.  $\gamma$ -Alumina formed initially in dry oxygen which later transformed to  $\alpha$ -alumina, with about 1% Fe-rich nodules. Hayashi *et al.*<sup>69</sup> found for an Fe-5% Al alloy at 800 °C a substantially lower growth rate in N<sub>2</sub>-20 vol.% O<sub>2</sub> than in N<sub>2</sub>-12.2 vol.% H<sub>2</sub>O. Malkow *et al.*<sup>43</sup> observed for an 18% Cr ferritic

steel containing 1.2% Al protective alumina scale formation after 1000 h exposure at 800 °C in air. However, in simulated SOFC anode gas (Ar-H<sub>2</sub>-H<sub>2</sub>O-(CO)), the alloy tended to form a Cr-rich surface oxide and internal oxidation of Al. The results for these borderline alloys might be related to enhanced internal oxidation of the protective scale-forming element Al due to hydrogen incorporation in the alloy, in a similar manner as described for FeCr alloys in [Section 1.17.4.3.2](#).

Another alloy system for which retarded protective alumina scale formation due to the presence of water vapor was described is the intermetallic phase  $\gamma$ -TiAl. On the basis of numerous studies,  $\gamma$ -TiAl can be considered as 'borderline alloy' because protective alumina scale formation in the temperature 700–900 °C has been shown to depend, for example, on the exact Al content, microstructure, surface treatment, alloying additions of, for example, Cr or Ag, and presence of microdopants such as halogens, etc.<sup>134–136</sup> Also, for this alloy system most of the studies in respect to the effect of water vapor relate to wet oxygen or wet air and only a few studies are available in low-*p*O<sub>2</sub> gases.

Niewolak<sup>137</sup> found protective alumina scale formation on a Ti-46.5Al-4(Cr, Nb, Ta, B) alloy after

**Figure 59** Weight changes during isothermal oxidation of Ti in Ar-H<sub>2</sub>O showing influence of temperature and water vapor pressure. Reproduced from Wouters, Y.; Galerie, A.; Petit, J. P. *Solid State Ionics* **1997**, *104*, 89–96.

96 h of isothermal exposure at 800 °C in Ar–20% O<sub>2</sub> (Figure 58). However, when oxidized in Ar–4% H<sub>2</sub>–2% H<sub>2</sub>O, rapidly growing, mixed Al<sub>2</sub>O<sub>3</sub>/TiO<sub>2</sub> base scales were formed (Figure 58). As above, this effect might have been caused by an enhanced internal oxidation of Al due to hydrogen incorporation in the alloy. Considering the morphology of the mixed Al<sub>2</sub>O<sub>3</sub>/TiO<sub>2</sub> scales, also H<sub>2</sub>O/H<sub>2</sub> bridges (Section 1.17.3.3) in voids could principally explain this effect, although in this alloy system this mechanism seems unlikely. The oxygen partial pressure in a void at the scale–alloy interface will be extremely low, for instance, at 800 °C in the range 10<sup>–43</sup> atm. Therefore, the equilibrium water vapor partial pressure in that

void would only be 10<sup>–14</sup> atm. This would, using the Langmuir equation (Section 1.17.4.4.2), result in a maximum rate of oxygen transfer of 5 × 10<sup>–13</sup> g cm<sup>–2</sup> s<sup>–1</sup>, which is far too low to sustain the oxidation rates observed by Niewolak<sup>137</sup> in the wet gas.

Another possible explanation for the nonprotective scale formation in Ar–H<sub>2</sub>–H<sub>2</sub>O would be that water vapor increases the growth rate of the nonprotective oxide, here TiO<sub>2</sub>, thereby, according to Gesmundo *et al.* (Section 1.17.4.3.3), increasing the critical Al content required for protective scale formation. Such an explanation may be derived from the results of Wouters *et al.*,<sup>138</sup> who reviewed the oxidation behavior of Ti in H<sub>2</sub>O containing gas. For example, after 25 h oxidation of Ti at 850 °C, the mass gain was higher by about a factor of 3 in 20 mbar H<sub>2</sub>O compared with the rate in 20 mbar O<sub>2</sub>. In the temperature range 650–850 °C, the rate of oxidation was directly proportional to the water vapor content, and approximately parabolic kinetics were observed (Figure 59). Hydrogen was found in the metal after exposure and there was no change in the conductivity of the oxide, which remained n-type. Wouters *et al.*<sup>138</sup> proposed that the increased rate of oxidation results from incorporation of OH<sup>–</sup> in the titania lattice and the more rapid diffusion associated with the smaller ionic radius than the oxide ion.

Niewolak<sup>137</sup> investigated the oxidation kinetics of γ-TiAl alloys in a number of dry and wet, high- and low-*p*O<sub>2</sub> gases. He found, that the change from a protective alumina base scale to a poorly protective TiO<sub>2</sub>-rich oxide layer (Figure 58) also occurred when decreasing the oxygen content in dry Ar–O<sub>2</sub> gases from 20% to less than 5%. The results thus indicate that the gas composition dependence shown in Figure 59 is at least to certain extent related to the differences in oxygen partial pressures of the test gases. Several authors<sup>139–141</sup> have shown that the dominating point defects in TiO<sub>2</sub> are oxygen vacancies at high oxygen partial pressure, whereas titanium interstitials dominate at low *p*O<sub>2</sub>. At 800 °C the oxygen partial pressure at which this change from one dominating defect type to another occurs is ~10<sup>–3</sup> bar.<sup>142</sup> It has also been shown<sup>143–145</sup> that the solubility of Al in TiO<sub>2</sub> increases with decreasing oxygen partial pressure, a factor frequently illustrated to be of great importance for oxide scale formation on γ-TiAl-based alloys. Decreasing the oxygen partial pressure of the gas thus not only changes the growth rate of the ‘nonprotective’ oxide TiO<sub>2</sub> but also the competition between formation of the alumina scale and its dissolution in TiO<sub>2</sub>.

## Glossary

**Converter** The containment for the industrial conversion of ore to metal and its purification by slag formation.

**Ellipsometry** Measurement of the change of light polarization upon reflection or transmission. In corrosion, it is usually done in reflection and used to infer the thickness of a very thin layer (down to the angstrom-level) of reaction product.

**Flue gas** Exhaust gases from a fireplace, oven, furnace, or other production process.

**Hot corrosion** Historically evolved name for the attack of a material by or involving salt melts. A typical representative is a  $\text{Na}_2\text{SO}_4$  melt.

**Hydrothermal** Conditions which involve a water fluid at elevated temperatures. Commonly used for conditions above  $100^\circ\text{C}$  at pressures above the atmospheric pressure.

**Ladle** Container for transport and pouring of (metal) melts.

**Rate constant** Constant which relates the quantitative progress of a process, example, a growth of a layer on an infinite plate, to time.

**Slag** By-product of ore smelting or refining. It usually consists mainly of oxides, with or without other constituents like sulfides, phosphates, and metals.

**Steady-state conditions** Conditions in which a system has a constant behavior with time. In corrosion, this often implies that external conditions such as the atmospheric partial pressure of the attacking medium are kept constant and a dynamic equilibrium is established, where two or more reversible processes occur at one rate.

**Thermogravimetry** Continuous instrumental determination of mass changes of a sample as a function of time, with or without regular changes in temperature, pressure, or gas composition during the observed time.

**Wetting angle** Contact angle at which the liquid-vapor interface of a fluid and the solid-vapor interface of a contacting solid meet. Describes the tendency of the fluid to form a film (perfectly at  $0^\circ\text{C}$ ) or a ball resting on the surface (perfectly above  $150^\circ\text{C}$ ).

## Abbreviations

**SEN** Submerged entry nozzle

**SSiC** Pressureless sintered silicon carbide

## Symbols

**A** Surface area ( $\text{m}^2$ )

**a** Thermal diffusivity ( $\text{m}^2 \text{s}^{-1}$ )

**C<sub>0</sub>** Concentration of carbon in liquid iron (wt %)

**C<sub>S</sub>** Saturation concentration of carbon in liquid iron (wt %)

**D<sub>i</sub>** Diffusion coefficient of component *i* ( $\text{m}^2 \text{s}^{-1}$ )

**D<sub>p</sub>** Pore-diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ )

**E** Modulus of elasticity (GPa)

**G<sub>F</sub>** Crack energy ( $\text{J m}^{-2}$ )

**ΔG<sup>0</sup>** Free enthalpy in the standard state ( $\text{J mol}^{-1}$ )

**g** Acceleration of gravity ( $\text{m s}^{-2}$ )

**h** Height (m)

**h<sub>l</sub>** Diameter of the convection loop (m)

**h<sub>g</sub>** Characteristic length of the corrosion groove (m)

**K** Equilibrium constant

**k<sub>linear</sub>** Linear rate constant ( $\text{m s}^{-1}$  or  $\text{kg m}^{-2} \text{s}^{-1}$ )

**k<sub>log</sub>** Logarithmic rate constant

**k<sub>p</sub>** Parabolic rate constant ( $\text{m}^2 \text{s}^{-1}$  or  $\text{kg}^2 \text{m}^{-4} \text{s}^{-1}$ )

**l** Length (m)

**P<sub>i</sub>** Partial pressure of species *i*

**R** Universal gas constant ( $8314 \text{ J mol}^{-1} \text{ K}^{-1}$ )

**T** Temperature (K)

**t** Time (s)

**u** Stoichiometry factor

**V<sub>l</sub>** Molar volume of phase *l* ( $\text{m}^3 \text{mol}^{-1}$ )

**v** Flow velocity ( $\text{m s}^{-1}$ )

**Δw** Mass change ( $\text{kg m}^{-2}$ )

**x** Mass change per unit area ( $\text{kg m}^{-2}$ ) or scale thickness (m)

**α** Thermal expansion coefficient ( $\text{K}^{-1}$ )

**β** Mass transfer coefficients ( $\text{m s}^{-1}$ )

**γ** Labyrinth factor, tortuosity

**δ** Boundary layer of diffusion (m)

**δ<sub>Pr</sub>** Prandtl's boundary layer thickness (m)

**δ<sub>N</sub>** Nernst's diffusion-boundary-layer thickness (m)

**p<sub>c</sub>** Open porosity of the decarburized zone (%)

**ε<sub>c</sub>** Critical elongation

**ρ** Density ( $\text{kg m}^{-3}$ )

**η** Dynamic viscosity ( $\text{kg m s}^{-1}$ )

**μ** Poisson ratio

- $\nu$  Kinematic viscosity ( $\text{m}^2 \text{s}^{-1}$ )
- $\sigma$  Interfacial tension ( $\text{N m}^{-1}$ )
- $\sigma_c$  Critical stress (MPa)
- $\theta$  Wetting angle ( $^\circ$ )
- $\tau$  Correction time (s)

### 1.26.1 Introduction

Ceramics are nonmetallic–inorganic materials, which are usually made by forming from a mass or a powder and firing at high temperature, upon which the material becomes consolidated and obtains its properties. This implies that ceramics have thermal and chemical stability at the firing temperature in the firing environment. ‘High temperature’ is a very blurred term, but most people would accept temperatures above  $800^\circ\text{C}$  as high temperature. An exception is the behavior in hydrothermal conditions. Hot, pressurized water is very reactive and many compounds have a high level of solubility in it. For this reason, we will describe the hydrothermal behavior of ceramics at lower temperatures.

A classical division of ceramics is silicate, oxide, and nonoxide ceramics. Textbooks and handbooks on their properties and manufacture have been published<sup>1–4</sup> and contain chapters on their corrosion resistance.

Metals and intermetallics do survive at high temperatures in many environments only because they form phases, commonly oxides, which protect them from further attack. In this respect, many chapters in this book deal with ceramics. In order not to repeat too many issues, readers are referred to appropriate chapters, in particular the ones on **Oxidation of Metals and Alloys** and **High Temperature Coatings: Protection and Breakdown**. In this chapter, we will deal with bulk materials.

There are many applications of ceramics at high temperatures: one deals with materials that contain and protect from melts in the metal or glass industry, another is the function to transport or contain heat in predominantly gaseous environments. For some tasks, structural loads under adverse conditions have to be met, whereas for others, several forms of attack may occur, e.g., waste incineration. A rather new application is the use of SiC as an electronic material, commonly in the form of single crystal wafers. Although the use is at low or moderate temperatures, a high temperature treatment to produce insulating silica is a common step in the production of these new functional materials.

A refractory material is firstly a ceramic that has not reached the softening point, at which a special pyramid (Seeger-cone SK17) would bend when heated to  $1500^\circ\text{C}$ . However, the material has to fulfill other criteria at high temperatures to be called refractory, namely, it has to keep its shape, survive thermal fluctuations, and withstand attack by slags or melts for a sufficiently long time.<sup>5,6</sup> Refractories are in most cases porous composites, making the behavior complex.

There is an overlap in materials chemistry between refractories and technical ceramics. For example, alumina and silicon carbide are manufactured both as refractories and as dense, advanced engineering ceramics. For this reason, refractories are dealt with in the form of typical examples from the steel- and iron-making industries. Other applications have similar principal problems and, from a chemical point of view, are contained within the ceramics section.

### 1.26.2 Differences between Metals and Ceramics

In the corrosion of metals, we usually find oxidation of the metal to form some phase, which is then lost to the environment by spallation, dissolution, or some other mechanisms, resulting in mass loss or the formation of a surface layer, which can have protective characteristics. Basic cases like the oxidation of iron are well known<sup>7</sup> and may be described by simple laws such as a parabolic weight gain in certain regimes.

The complexities of scale evolution often necessitate a more complex modeling of the transport in oxide scales, and finite difference calculations are used to predict the process progression.<sup>8</sup>

The importance of the oxide development in silicon-based semiconductors has led to the development of sophisticated detailed models for high temperature oxidation, whether related to initial periods<sup>9</sup> or general laws.<sup>10</sup>

Ceramics are often oxides, carbides, or nitrides. In general, nonmetals have a higher electronegativity than metals. The bonding is mostly a mixed ionic–covalent one, but formally the electrons have to be assigned to the nonmetal. High temperature oxidation of these carbides and nitrides thus oxidizes the carbon or the nitrogen and leaves the metal or semiconductor in its oxidation state. Also, in contrast to metals, where often the metal is transported as an ion to the surface to become oxidized, in ceramics we usually have the transport of the corroding agent to

the scale–substrate interface where reaction occurs. The oxidation process is therefore better compared with semiconductors rather than with ordinary metals.

Oxide ceramics are stable in environments having sufficient oxygen; their corrosion is based on reactions that form other phases, becoming dissolved or evaporated.

### 1.26.3 Corrosion Modes and Kinetics

To understand the principles, we first assume the material to be single phased, isotropic, dense, and to have perfect surfaces. Just like metals, ceramics can show both active and passive corrosion behaviors. Unless retarding phases are formed, steady-state processes in active corrosion have simple and constant mass loss rates for a given set of physical boundary conditions. It does not matter whether the chemical reaction rate, the dissolution kinetics, or the diffusion from or into the corrosive medium is rate determining. The constancy of boundary conditions such as constant gradients in the attacking agent necessitates linear kinetics following eqn. [1], in which  $x$  denotes either the thickness of the layer lost or the mass of material loss per unit area,  $t$  the time, and  $k_{\text{linear}}$  is the linear rate constant:

$$x(\text{m or kg m}^{-2}) = k_{\text{linear}}(\text{ms}^{-1} \text{ or kg m}^{-2} \text{ s}^{-1}) \cdot t(\text{s}) \quad [1]$$

The time to reach those steady-state conditions is not covered by the model, so initial periods with differing rates are possible. In the initial period, transport-related problems are less likely to dominate, so formation or removal of surface adlayers may lead to incubation periods. Alternatively, the buildup of a gradient may be fast in the beginning and turn into a steady-state rate later.

The ease of this formulation hides the problems associated with it. Everything rests on the constancy of external conditions, and therefore the measured rates depend on a large number of boundary conditions. Laminar or turbulent flows of the attacking medium, convection or still conditions, and flow velocity of the attacking gas or fluid are only a few obvious parameters.

For polyphasic materials, the resistance against attack is usually different for the different phases. Here, eqn. [1] is only valid for each phase individually and only as long as the processes do not influence each other. The example of a preferential grain boundary phase attack is easy to understand. Here,

boundary phase removal concurrent with a more or less inert matrix material gives us the picture of increasing pathway lengths for the attacking agent with time. This is very likely to slow down the corrosion progress. In such cases, eqn. [1] is correct for neither the bulk material nor the individual phase.

Porous materials have another prominent problem: establishing contact with the medium so that the development of transport pathways becomes complex. Wetting behavior is of utmost importance, as it governs the penetration and hence the true contact surface. Wetting depends on surface energies and these are likely to change with time due to gradient developments, saturation effects, etc. Such problems are dealt with in detail in Section 1.26.14 on refractory corrosion in the form of typical examples and equations.

Although the chemical removal of phases is a corrosive process, it may well be influenced by erosive or mechanical stresses accompanying the attack. This is also described in the refractory section of this chapter (Section 1.26.10). At this point, we only want to hint that the formation of a solid reaction product during corrosion may not always retard the corrosion progress. Such a special form of active corrosion, which is particular to nonoxide ceramics, has been described for silicon carbide at very high temperatures,<sup>11</sup> where a high pressure of CO can create bubbles, which are easily removed by spallation and erosion.

The formation of solid phases during corrosion can often result in scales or layers. It depends on their physical nature whether they hamper the corrosion process or not. Oxide scales on nonoxide ceramics often do not have such a high mismatch in thermal expansion coefficients as oxidized metals. Hence, stresses in the scale can be lower and spallation is a less common phenomenon. Nonetheless, the oxides can undergo phase transitions with volume changes large enough to cause stresses and cracking during thermal cycling. Multiphase scales likewise can develop stresses that induce cracks. Bubbles are another way of potentially short-circuiting the scale.

In all such cases, eqn. [1] is also valid for passive corrosion, because the scale that develops is not protective. The equation has then positive constants for mass gain. Also in any real process where a scale becomes protective, there is an initial period, in which it is not thick enough to be rate determining. This has been established for the oxidation of silicon by Deal and Grove,<sup>10</sup> where the linear character of the initial period has been shown.

In both metals and ceramics, corrosion in which the transport of the reacting agent through a growing layer is governed by the diffusion of this agent or the reaction product through the scale, we have long-time behavior approximated by a simple parabolic law

$$x(\text{m or kg m}^{-2}) = \sqrt{k_p(\text{m}^2 \text{s}^{-1} \text{ or kg}^2 \text{m}^{-4} \text{s}^{-1}) \cdot t(\text{s})} \quad [2]$$

In eqns. [2]–[5],  $x$  now denotes either the thickness of the layer formed or the mass of material gained per unit area,  $t$  is the time, and  $k_p$  is the parabolic rate constant. Following the reasoning above, both parts of the process can be joined with the linear–parabolic model<sup>10</sup> to give

$$x^2 + Ax = B(t + \tau) \quad [3]$$

in which several physical parameter are contained in the factors  $A$  and  $B$  and a correction time  $\tau$  is introduced, which accounts for an initial scale thickness. By setting reasonable boundary conditions, it is found that  $B$  equals  $k_p$  for long times and thus eqn. [3] is approximated by eqn. [2],  $B/A$  equals  $k_{\text{linear}}$  and thus eqn. [3] is approximated by eqn. [1] for short times. Note that ‘short times’ is an expression relating to corrosion progress and can last, for example, for days at 700 °C in the oxidation of silicon.

It was claimed that the oxidation data for silicon can equally well be fitted by a simple power law<sup>12</sup>

$$x = at^b \quad [4]$$

This method has not been used extensively in the literature for oxidation of semiconductors or ceramics. The lack of a good physical explanation for the parameters of eqn. [4] is probably the main reason.

For easy fitting, a variant of eqn. [3] may be preferred:

$$\frac{x^2}{k_p} + \frac{x}{k_l} - \tau = t \quad [5]$$

A difference to be noted between ceramics and metals is that the corrosion progress  $x$  is not directly transferred from thickness to weight change units via densities  $\rho$ , because in nonoxides there is a loss of the accompanying light element. As described elsewhere,<sup>13</sup> a stoichiometry factor relating to the reaction equation

$$u = \frac{(n \cdot M)_{\text{Condensed product}}}{(n \cdot M)_{\text{Condensed product}} - (n \cdot M)_{\text{Material}}} \quad [6]$$

where  $n$  is the number of moles in the chemical reaction equation and  $M$  the molecular weight, has

to be calculated to relate rate constants to each other by eqn. [7]:

$$k_p(\text{m s}^{-1}) \frac{\rho_{\text{Product}}^2(\text{kg m}^{-3})^2}{u^2} = k_p(\text{kg}^2 \text{m}^{-2} \text{s}^{-1}) \quad [7]$$

A third basic law is the logarithmic or asymptotic law

$$x = c + k_{\log} \log(t) \quad [8]$$

This may be used for corrosion processes, which are effectively stopped by the formation of a material barrier during corrosion. It basically describes the decrease in the effective exposed surface area. The barrier may be a crystalline phase with a much lower diffusion coefficient.

Kinetic breaks are observed in cases where a physical effect interferes with the corrosion process. An example is the repeated cracking of the scale. If a critical thickness is responsible for the critical stress, which initiates the cracking process, pseudolinear behavior with a succession of periods of parabolic growth and intervening periods of renewal of short-circuiting paths follows.

Internal oxidation is observed in multiphase ceramics. A grain boundary phase is often the weakest material in terms of corrosion resistance and provides a transport path for the exchange of matter between the inside and the outside of the structure. The production of selectively corroded phases in the interior induces internal stresses because of volume increases. After a critical stress level is reached, mechanical failure of parts of the component near the surface may follow. If this cannot be healed during the process, a large new surface area is opened and a ‘break-away’ situation is likely, i.e., a change to fast linear corrosion.

Another typical break situation is observed in porous materials. The closure of pore openings by the formed scale diminishes the exposed surface markedly and almost instantaneously. A much slower progress follows after closure.

Simple basic laws of passive processes are only true for constant diffusion coefficients. In all cases, where extrinsic or intrinsic impurities, additives, etc., are present and enter the scale forming material, an influence on the diffusion coefficient must be envisaged. An increase or decrease in the coefficient causes the mass change curve to become steeper or flatter relative to parabolic behavior. Simulations show that for strong effects of this kind linear [1] or asymptotic behavior [7] is approximated.

Therefore, we have good reasons to envisage complex kinetic behavior during corrosion to be possible.

Complex strictly physical models are a matter of model calculations still and hard to generalize. Attempts to model complex situations by semi- or purely empirical curve fitting procedures, e.g., by using a multiple linear approach in the form

$$x = k_0 + k_{\text{lin}}t + k_p''\sqrt{t} + k_{\text{log}}\log(t) \quad [9]$$

have been proposed<sup>14, 15</sup> and shown to be quite successful. Attempts to introduce an even higher degree of sophistication made the equations less robust to the errors inherited from the uncertainties of measurement.<sup>16</sup>

A special case of complex kinetics arises from situations in which active and passive processes occur simultaneously. This has been discussed extensively because it is of great importance to applications such as gas turbines.<sup>17</sup> Corrosion in which a scale is formed and evaporated at the same time has a typical pattern in plots of mass change against time, because the initial gain will turn into a linear loss after longer times. Opila<sup>18</sup> has shown that the equation for metal oxidation with evaporation reported by Tedmon<sup>19</sup> in the form

$$t = \left[ \frac{u_1^2 k_p}{2k_1^2} \left[ -\frac{2k_1 \Delta w_1}{u_1 k_p} - \ln \left( 1 - \frac{2k_1 \Delta w_1}{u_1 k_p} \right) \right] \right] - \frac{\Delta w_2}{u_2 k_1} \quad [10]$$

where  $u_1$  and  $u_2$  are stoichiometric factors, which account for the mass balance of the appropriate reactions,  $\Delta w_1$  and  $\Delta w_2$  are weight gain and weight loss by scale growth and volatilization, respectively, is successful in describing this steady-state situation, leading to the establishment of a steady-state scale thickness and progressing corrosion of the material. The engineering basis for the loss function was also explored and simulated with parameters for the flow of fluids.<sup>20</sup>

### 1.26.4 Corrosion Measurement

In situ experiments of ceramic corrosion can only be done for simple cases. Simple oxidation of a nonoxide in a defined atmosphere can be followed continuously by thermogravimetry (TGA), which allows proper kinetic modeling. Resolution, accuracy, precision, and long-time stability of the apparatus have to be controlled. Other problems, e.g., contamination or the creation of local atmospheres, are identical to those discussed below.

Scale growth monitoring measurements, e.g., by ellipsometry, which are common for oxidation of silicon, have rarely been used in ceramics. Only in recent years, with SiC wafers for electronic applications becoming available, have such data been produced in greater numbers.

The most common experiments in ceramics corrosion are still exposures in special environments, followed by weighing and inspecting with microscopic and other available analytical techniques.

Melt corrosion is often studied by ordinary drop, crucible, and finger tests; these should only be used to rank materials, because they give qualitative data inside a narrow frame set by the standardized experimental setup.

Burner rigs are used to test for salt melt corrosion ('hot corrosion').<sup>21</sup> Salts are injected into the flame of a burner and deposited at constant rates onto samples, which are positioned and agitated in front of the apparatus exhaust.

Post-inspection of samples from furnace tests is most common for the investigation of interactions with gases. As a typical example for the contamination problems associated with the method, we can look at protective tubes made from alumina. Most gases, even expensive high-purity types, do contain water at the ppm-level. Unless the alumina tube was fired and flushed at high temperatures for times in the order of 1000 h, it may contaminate the sample with sodium, and as long as extreme measures have not been taken to dry the atmosphere (e.g., by  $\text{P}_2\text{O}_5$ ), there may be substantial contamination by alumina in the form of transfer as hydroxide.<sup>22</sup> In deliberately moistened atmospheres, the effect is quite high.<sup>23</sup> The effect on oxidation rates for silica formers has been shown to be extensive even for low contamination levels,<sup>24</sup> because the contaminants are good glass formers, and may change the properties of growing scales. Apart from contamination, local atmospheres may play a role, which may explain the observed influences of furnace size on experimental oxidation rates.<sup>25</sup>

High temperature experiments have always an extended level of contamination possibilities. An increased level of uncertainty in corrosion data comes also from sample inhomogeneities. Preferential corrosion of secondary or grain boundary phases is often calculated directly relative to the total sample surface and yields a corresponding bias in parameter evaluation. Adding the increased uncertainty levels of temperature measurement and physical side effects such as the relative large areas in the vicinity of an edge in the usually small

samples, it is plain that one has to allow for some systematic and statistical error in the experimental data.

## 1.26.5 Oxides

A number of oxides with high melting points could qualify as high temperature materials. Out of these only a small number is used as bulk engineering material, and therefore only alumina and zirconia are dealt with here in detail. The other oxides are either covered by the chapter on “Oxidation of Metals and Alloys” or are covered by the chapter on **Oxidation of Metals and Alloys** or are contained within the refractory sections of this chapter.

### 1.26.5.1 Alumina

The only form of alumina that is stable at high temperature is corundum or  $\alpha$ - $\text{Al}_2\text{O}_3$ . It is well known for its excellent chemical resistance, even at high temperatures. For this reason, it is a common tube material in high temperature furnace systems with oxidizing atmospheres. The applications at high temperature are often limited by other properties rather than corrosion, namely creep and poor mechanical properties.

Nonetheless, there are some restrictions for the use of alumina based on its chemical behavior. At temperatures of 1700 °C in Ar/ $\text{H}_2\text{O}$  mixtures, evaporation of alumina was reported and excessive grain growth may have enhanced the problems.<sup>26</sup> Reducing environments can also foster carbothermic reduction of alumina, e.g., in the presence of SiC,<sup>27</sup> but in general a good resistance to flue gases of the aluminum-remelting industry has been reported.<sup>28</sup> The attack by alkali metal vapors is impurity dependent.

Corrosion by aggressive gases can be estimated via calculation of the partial pressures of volatile species over alumina.<sup>29</sup> This has been shown for halogens<sup>30</sup> and is certainly true for other such agents. The vaporization in water containing systems is mainly in the form of  $\text{Al}(\text{OH})_3$ . Therefore, in high-velocity gas streams containing water, there is a limitation for long-time applications.

Solid-state reactions for silica are not restricted to phase equilibria with mullite, because the system is complicated and characterized by metastable immiscibility gaps at temperatures significantly below the eutectic value close to 1600 °C. Alumina is a common component in, and therefore can be dissolved by, silicate slags. For the details of the process dependencies, the reader is referred to example references.<sup>31</sup>

The corrosion resistance of alumina ceramics is strongly influenced by impurities because some of

these are incorporated as grain boundary phases with accordingly selective preferential damage. In particular, silica and alkalis are typical impurities for alumina in engineering ceramics and even small amounts have been shown to be responsible for the corrosion in hydrothermal conditions.<sup>32</sup> Similarly corrosion by salt melts is related to impurities and grain boundary phases.<sup>33</sup>

### 1.26.5.2 Zirconia

Zirconia ( $\text{ZrO}_2$ ) is a high temperature phase with a melting point above 2500 °C. Extremely high values even for the lowest eutectic temperatures in the binary systems with alumina and silica make it a prime material for refractory systems by itself or with those oxides. For many conditions, it will behave in an almost inert manner in contact with silica or alumina.

The section on thermal barrier coatings in this book discusses the corrosion aspects in those high temperature applications.

As a pure monolithic material, it is more problematic, because martensitic phase transformations with volume changes occur and tend to embrittle the material during thermal cycling. The addition of Mg, Ca, Y, and Ce stabilizes the higher temperature modifications (for a review on the basic science of these transformations see Hannink *et al.*<sup>34</sup>), and with appropriately high concentrations the cubic modification is stable down to room temperature.

In a stabilized modification, the use of zirconia as a refractory material is possible. Such refractories are susceptible to corrosion by slags, because slags with low basicity leach MgO, and highly basic slags can dissolve the material completely. Applications in remelting furnaces showed a good resistance to flue gases.

The stabilization can have deleterious effects on Ce-doped materials because the variation of external oxygen fugacity can induce corrosion due to a change in the oxidation state. Corrosion by water is a serious problem because even at low temperatures it can enter the structure of zirconia and destabilize the modifications. Appropriate phase transformations have been observed under hydrothermal conditions.<sup>35</sup>

### 1.26.5.3 Cordierite

Cordierite ( $\text{Al}_3\text{Mg}_2(\text{Si}_5\text{AlO}_{18})$ ) is a rock-forming mineral, and the pure Mg-end member of the solid solution with Fe melts incongruently at 1460 °C to yield mullite and liquid. It is a widely applied ceramic for soot filters or heat exchanger, because it

has a low thermal expansion coefficient and therefore is very tolerant to thermal shocks and cycling.

High temperature corrosion of cordierite is known from treatments with molten salts (hot corrosion).

## 1.26.6 Carbides

### 1.26.6.1 Boron Carbide

Hydrothermal corrosion of  $B_4C$  proceeds at low pressures and C:H-ratios according to reactions of the type

in which  $CO_2$  is replaced by methane or carbon monoxide under appropriate carbide/water ratios. In analogy with water vapor systems, reactions start at temperatures as low as 250 °C because no carbon layer is produced.

Experiments on the attack by oxygen on powders,<sup>36</sup> coatings, and sintered materials confirm that at low and moderate temperatures the oxidation yields boric acid

and the kinetics are governed by oxygen diffusion through it. In the high temperature regime, starting at about 800 °C, boric acid evaporates and the process becomes parabolic with an overall loss at longer times. Evaporation is stronger in wet atmospheres, because the reaction

dominates at temperatures below about 1000 °C with high partial pressures. Boron carbide was investigated in steam because it is an important material in the nuclear industry. The dependence of the kinetics on partial pressures of water and flow speed was confirmed and modeled.<sup>37</sup> It should be noted that many commercial bulk boron carbides contain impurities or additives, which strongly influence the process.<sup>38</sup>

### 1.26.6.2 Silicon Carbide

Corrosion data collections for SiC-based materials are found in a number of handbooks and textbooks,<sup>39–42</sup> are contained in specific conference proceedings<sup>14,43,44</sup> and a vast number of publications. The interest in the high temperature behavior of this material comes historically from its use as a refractory material, later from the structural engineering

advanced ceramics, and in recent times, increasingly from the need to understand the behavior to obtain insulating parts within a semiconductor.

Hydrothermal corrosion is significant only at temperatures exceeding 500 °C, even though initial reactions may occur at 300 °C. The hydrothermal oxidation yields silica along with  $CH_4$ ,  $CO_x \pm C$ . The attack is commonly an active corrosion, because silica is dissolved in  $H_2O$ . The dissolution rate of silica is the key to the kinetics of the process and can be modified by increasing the pH of the water. The onset of hydrothermal oxidation in silicon nitride, likewise forming silica, is at much lower temperatures. The difference indicates protection by the formation of carbon layers at temperatures below about 500 °C, which has been observed for SiC-based fibers<sup>45</sup> and in halogen containing environments.<sup>46</sup>

Silicides are thermodynamically often more stable than SiC and a number of low-temperature eutectics exist with SiC. Therefore, metals can corrode SiC and a compilation<sup>41</sup> gives indications for reactions with Al (750 °C), Au (950 °C), Bi (600 °C), Cr (1000 °C), Cu (950 °C), Co (1150 °C), Fe (1000 °C), Li (815 °C), Mg (800 °C), Ti (575 °C), Mo (1200 °C), Nb (1300 °C), Ni (500 °C), Pd (600 °C), Ta (1200 °C), and W (1500 °C). Resistance to the attack was noted for Ag (962 °C), Ca (1180 °C), Cd (500 °C), Na (350 °C), Pb (815 °C), and Sn (600 °C).

Most of those data were obtained in vacuum, where the wetting behavior, which is essential for the form and strength of attack, is different from oxidizing conditions. It should also be noted that SiC containing free Si reacts more readily than SiC. Temperatures of possible reactions may be evaluated with the aid of phase diagrams of the appropriate Si-metal system. In appropriate wear conditions, a reaction of SiC with a metal is therefore feasible.

For attack by salt melts (hot corrosion), the reviews by Jacobson and coworkers<sup>47–49</sup> are still fundamental. As explained in the appropriate chapter in this book, the attacking salts are best represented by  $Na_2SO_4$ , which forms in combustion environments by

A first condition for a window of effective hot corrosion is given by the melting and dew points of  $Na_2SO_4$ . The melting point is 884 °C, the dew point varies with pressure, S content of the fuel, and NaCl concentration in the atmosphere. In gases with  $NaCl > 1$  ppm and combustion pressures of 100 bar, the dew point ranges between 1100 and 1200 °C (from eqn.[14]).

The corrosive effect is not a reaction with the sulfate. It is due to the activity of  $\text{Na}_2\text{O}$  from the decomposition

and reaction with the protective  $\text{SiO}_2$  scale

Therefore, other compounds releasing alkali oxide on decomposition, e.g.,  $\text{Na}_2\text{CO}_3$ , also cause hot corrosion.

Reaction [15] shows that a low  $P(\text{SO}_3)$  value drives reaction [16] to the right side, typical for the external  $P(\text{SO}_3)$  from the combustion of low-S fuels ( $<0.5\%$ , a condition met by many modern fuels) at temperatures of about  $1000^\circ\text{C}$ .

However, corrosion starts at the melting point of  $\text{Na}_2\text{SO}_4$ . Free carbon is often present in commercial SSiC (=pressureless sintered silicon carbide) and promotes the dissociation of  $\text{Na}_2\text{SO}_4$  by making the silicate melt more basic. Accordingly, very strong hot corrosion of SiC with free carbon is known.<sup>50</sup>

Even without free carbon hot corrosion of SiC should occur as an internally governed process analogous to studies<sup>51</sup> on  $\text{Si}_3\text{N}_4$ , because SiC may act as the reducing agent to promote sulfate dissociation directly or by establishing an oxygen gradient in the silica scale consumed by reaction [16].

Hot corrosion tests are often only qualitative. Even burner-rig methods have problems for quantifying the attack. In terms of degradation of the mechanical properties, it should be noted that hot corrosion

commonly causes pitting with a change in exposed surface and nonuniform attack. Pitting may not in all cases be a secondary phase problem, because it can be initiated by the immiscibility of two liquids.<sup>51</sup> It seems to be fairly difficult to model the damage by hot corrosion in a general way. One approach is to relate the pit diameter to strength data, i.e., to treat them as critical flaw sizes in the Griffith equation.

Hot corrosion protection has been investigated using mullite coatings.<sup>17</sup> Some temporary protection may even come from simple silica coatings.<sup>52</sup>

The corrosion of SiC by hot gases has been the subject of many studies. Active corrosion is a form of attack by gases, which do not form condensed species with Si at the temperatures of interest. Thus, halogens induce active corrosion, and calculated pressures of species such as  $\text{SiF}_4$  or  $\text{SiCl}_4$  over SiC will be as high as the concentration of F and Cl in the gas.

These pressures will be significantly decreased and the damage is less severe in the presence of oxygen, as evidenced by a study on  $\text{Cl}_2$  corrosion.<sup>53</sup>

Corrosion of pure SiC by  $\text{H}_2$  starts at temperatures above  $1300^\circ\text{C}$ , while grain boundaries and secondary phases in sintered SiC are attacked at temperatures as low as  $1000^\circ\text{C}$ .

The formation of silica is therefore essential for the stability of SiC. The boundary for active-to-passive oxidation is described in Figure 1. Wagner-type models predict the transition for diffusion-related situations and are relatively successful. From experimental evidence at temperatures of  $\sim 1760^\circ\text{C}$ ,<sup>54</sup>

**Figure 1** Active-to-passive transition of SiC thermal oxidation calculated (CC) from Wagner-type models and volatility diagrams and experimental values on single crystals (SC) and SSiC (PLS), see Presser and Nickel.<sup>56</sup>

a secondary active-to-passive transition was formulated, at which the formed silica spalled because of a CO interface pressure exceeding ambient pressures.

Oxygen pressures in **Figure 1** should not be confused with data from  $\text{CO}_x$  experiments, because CO is a reactive and an oxidizing gas species for SiC<sup>41</sup> despite a low oxygen partial pressure. Therefore, active oxidation in CO is only observed at very high temperatures.<sup>55</sup>

The silica formation in the passive regime at high temperatures is in detail a complex process, which includes several stages of amorphous silica formation and its crystallization. A review will be given elsewhere.<sup>56</sup> At temperatures below about 1200 °C a linear-parabolic model in the sense of Deal and Grove<sup>10</sup> is necessary to explain the oxidation data, whereas at higher temperatures a simple parabolic law is usually sufficient.

The process is still not well understood, because the rate constants are clearly dependent on the exposed crystallographic face of SiC,<sup>57</sup> and at the same time it is believed that it depends on the diffusion of oxygen through silica, because the kinetics are parabolic and activation energies fit this process.<sup>58</sup> However, at temperatures above about 1300 °C, there are data sets indicating a high activation energy,

compatible with network oxygen diffusion in amorphous silica rather than molecular diffusion. It has been argued that this is related to extrinsic impurities from the experimental setups.<sup>59</sup>

In a plot compiling rate constants from a large number of data for fairly pure SiC (CVD, single crystals), including differing crystallographic faces, the situation is not so straight-forward,<sup>56</sup> but a fairly high spread of parabolic rates is evident (**Figure 2**).

Commercial qualities of sintered SiC often have low impurity or additive contents and have rates as low as pure materials, indicating extremely good oxidation resistance up to very high temperatures. This is certainly not really true for  $T$  above 1600 °C, because at very high temperatures the long-time kinetics are not adequately described by the parabolic law, the problem of active II oxidation is important and in addition bubble-and-pit formation, which is usually attributed to additives containing boron and/or aluminum, is likely to endanger applications (**Figure 3**). It should also be noted that bubble-and-pit formation can occur after an ‘incubation period’ of several 100 h at  $T > 1600$  °C, while oxidation studies run usually only for times <100 h. Therefore long-time studies may be necessary for a true qualification of SiC at extremely high temperatures.

**Figure 2** Comparative plot of parabolic rate constants. The plot comes from Presser and Nickel<sup>56</sup> where the data sources are referenced.

**Figure 3** Bubbles at the surface of SSiC oxidized at 1500 °C for 24 h under humid conditions and pits beneath (1500 °C, 50 h) revealed by HF-etching of oxidized SSiC from Ref. 100.

Furthermore, good resistance to oxidation by O<sub>2</sub> or air does not guarantee equally good behavior in complex industrial environments. Other components of the atmosphere or extrinsic impurities can change the behavior markedly and make a prediction difficult in cases of strong variations in temperature and gas composition, even though resistance of SiC-based materials to other aggressive environments, e.g., such as SO<sub>2</sub> or H<sub>2</sub>S, has been reported.<sup>14</sup>

For such environments, case studies give an indication but are not unambiguous.<sup>14</sup> SSiC was reported to resist flue gases of aluminum-remelting furnaces up to 1000 h without much change in strength in one study but had problems in others. The strength of SSiC was unchanged in nitrogen-based gases of the system N<sub>2</sub>–H<sub>2</sub>–CO, but decreased up to 50% in endothermic gases at 1200–1300 °C in long-time experiments.

Water enhances the oxidation of SiC only slightly, but the transport of extrinsic impurities because of water can strongly enhance oxidation and the limitations in applications with high gas flow rates because of vaporization of the silica scale inducing parabolic behavior are known.<sup>60</sup>

## 1.26.7 Nitrides

### 1.26.7.1 Silicon Nitride

Silicon nitrides are often discussed together with silicon carbides, because both materials are silica formers. For this reason, data collections and textbook sections are identical to those already cited for carbides.<sup>13,14,39,40,42–44</sup> For an additional, detailed study see Ref. 61. A typical difference from the silicon carbides is the much higher additive content of almost all commercial sintered silicon nitrides. Only liquid-phase sintered SiC types ('LP-SiC') have comparably high amounts.

Hydrothermal corrosion of silicon nitride starts at about 130 °C because of the high solubility of silica in water under high pressure. The reaction

does not passivate because the dissolution of NH<sub>3</sub> makes the solution caustic, which strongly enhances silica solubility. Therefore, reaction kinetics are linear and active corrosion prevails.

The hydrothermal corrosion of the grain boundary phase of Si<sub>3</sub>N<sub>4</sub> ceramics can be very strong and pit formation was observed at 300 °C and 8.6 MPa.<sup>62</sup> From experiments on hot isostatically pressed silicon nitride (HIPSIN), which were free of additives other than silica, we know that preferential hydrothermal leaching of silica as the grain boundary phase can cause grain dislodgment.<sup>63</sup>

A compilation of data for the reactions of Si<sub>3</sub>N<sub>4</sub> with metals and alloys has been given in Ref. 64. The interaction is important for bonding to metals; often silicides or other ternary compounds are formed. The interaction of the related SiAlONs (silicon nitrides, which incorporate alumina and yttria in their lattice) and alloys was found to be similar. In inert gas atmosphere or under vacuum, Si<sub>3</sub>N<sub>4</sub> reacts readily with most transition elements below 1000 °C and with many other metals at various temperatures, while protection by silica in oxidizing conditions is effective for some conditions.<sup>64</sup>

Hot corrosion of Si<sub>3</sub>N<sub>4</sub> attacks the silica scale and the behavior is therefore similar to that of SiC, as confirmed by studies at NASA labs.<sup>48,65</sup> However, the initial process may be governed by intrinsic factors, because surface tension differences between sulfate and silicate melts result in a fractal pattern of hillocks of silicate melt beneath the sulfate. This was reported to enhance local corrosion and induce pit formation. The process slows down with time and

therefore  $\text{Si}_3\text{N}_4$ -based ceramics can serve well under hot corrosion conditions. Even though there is a degradation in mechanical properties similar to that of SiC,<sup>21,66</sup> the remaining strength after hot corrosion of the nitride is higher than that of SiC.

Active corrosion of  $\text{Si}_3\text{N}_4$  ceramics by hot gases is often stronger than comparable attack on SiC, because the grain boundary phase removal causes grain dislodgment and inhomogeneous internal corrosion. In particular, halogens create high partial pressures of Si-bearing species and accordingly strong active corrosion, but small amounts of oxygen or water can significantly decrease the effect of  $\text{Cl}_2$  or sulfidizing environments by silica formation. The active-to-passive transition occurs at similar conditions as the one for SiC (Figure 1).

From thermodynamic considerations<sup>67</sup> the passive oxidation of pure  $\text{Si}_3\text{N}_4$  should involve a two-step oxidation

forming a duplex layer in an oxygen potential gradient. A definitive proof for a sublayer of  $\text{Si}_2\text{N}_2\text{O}$  was only provided for pure nitrides,<sup>68</sup> but a superior

oxidation resistance for pure  $\text{Si}_3\text{N}_4$  compared with that for SiC at temperatures of about  $1500^\circ\text{C}$  is evident and contrasts with the behavior of sintered  $\text{Si}_3\text{N}_4$ . This is plain from Figure 4, which shows calculated critical times  $t_c$  for  $100\text{ }\mu\text{m}$  penetration on pure and sintered nitride and carbides, assuming parabolic growth and using the data compiled earlier.<sup>13</sup>

The presence of grain boundary phases is the main reason for the pronounced decrease in oxidation resistance. In detail, a number of processes, including the leaching of grain boundary constituents to the scale, crystallization, internal oxidation, bubble formation, and scale cracking, occur and vary with amount and exact composition of the additives. The discussion of such processes is referenced in the textbooks cited at the beginning of this chapter.

Again, it must be noted that the data in Figure 4 should serve as an indication only, because the values were calculated assuming a truly simple parabolic behavior, which is often not really fulfilled.

### 1.26.7.2 Boron Nitride

In hydrothermal conditions, BN is attacked at temperatures as low as  $150^\circ\text{C}$ , following linear kinetics.<sup>69</sup> Hexagonal BN is often applied in the production of the metal and for thermocouples in Fe alloy melts, which is ample evidence for a good corrosion resistance against metal melts and slags at much higher temperatures, namely alkali halides, lithium borate, and cryolite. This is due to the poor wetting behavior of such melts on BN.

Only molten alkali carbonates and hydroxides decompose boron nitride by the reactions of the type

The product of the oxidation of boron nitride at atmospheric and low pressures is boric acid

and therefore the material has a similarity to boron carbide. The melting point of boric acid at  $410\text{--}450^\circ\text{C}$  keeps the formed oxide liquid at high temperatures. Accordingly, at temperatures exceeding  $700^\circ\text{C}$ , there is parabolic oxidation with the loss of boria by evaporation.<sup>70</sup> Water enhances the evaporation process, because the partial pressure of hydrogen-bearing species is high<sup>71</sup> and the oxidation can be described as

**Figure 4** Logarithm of calculated critical times in years for  $100\text{ }\mu\text{m}$  penetration for silicon nitrides (full symbols) and silicon carbides (open symbols) vs. temperature from compiled parabolic rate constants.<sup>13</sup>

### 1.26.7.3 Silico-Carbonitrides

The precursor-derived amorphous silico-carbonitrides have high thermal stabilities, a boron-containing type reportedly up to 2000 °C.<sup>72</sup>

Crystallization may induce detrimental reactions as was shown for pure carbonitrides at ≈1400–1500 °C.<sup>73</sup> Their nominal stoichiometry has C in addition to Si<sub>3</sub>N<sub>4</sub> and SiC and therefore the reaction

takes place at about the thermodynamically predicted temperature (≈1405 °C at 1 bar N<sub>2</sub>). Oxidized samples without such a reaction<sup>74</sup> were observed to survive because of an internal pressure buildup of several bars.

As suggested earlier,<sup>75</sup> carbonitrides are susceptible to hot corrosion because the excess carbon will tend to make a melt basic. In terms of oxidation resistance, the data<sup>76–78</sup> suggest that they have very low oxidation rates at temperatures up to 1600 °C. The problem of bubble formation seems to be avoidable by Al incorporation in the ceramic. However, the penetration rates are probably not much better than those for pure silicon nitrides, and the problem of parabolic behavior in fast-flowing gases is valid for these materials as well.

### 1.26.8 Titanium Compounds

TiC and TiN show a very wide range of stoichiometry and form solid solutions in the Ti–C–N system. Thermodynamic equilibria in water–carbide systems<sup>79</sup> indicated that carbon, corresponding oxides, CH<sub>4</sub>, CO<sub>2</sub>, CO, and H<sub>2</sub> are the main products of hydrothermal corrosion of metal carbides in the temperature range 300–1000 °C. No protective oxide layers were formed upon hydrothermal corrosion of carbides of transition metals, but Raman spectra from hydrothermally treated TiC powders demonstrated the presence of graphite.

Oxidation of TiN powders, films, and sintered bodies<sup>80,81</sup> showed that oxidation occurs at very low temperatures and becomes significant at about 500 °C, with the formation of TiO<sub>2</sub>. Scales from titania are usually not protective at temperatures above 800 °C, which limits the use of monolithic titanium compounds at high temperature.

TiB<sub>2</sub> forms titania and boria and is known primarily for coatings and composites. Oxidation of

TiB<sub>2</sub> is significant above 700 °C and shows parabolic kinetics at those temperatures.<sup>82</sup> In powder experiments, an onset of oxidation was found at 400 °C and TiBO<sub>3</sub> was an oxidation product at low temperatures.<sup>83</sup> At 950 °C, the evaporation of B<sub>2</sub>O<sub>3</sub> becomes significant and parabolic oxidation occurs. However, unlike for boron carbide and nitride, the kinetics become parabolic again at higher temperatures (>1200 °C). This is explained by the fact that, when B<sub>2</sub>O<sub>3</sub> is completely evaporated, the process is controlled by diffusion through the titanium dioxide film.

Impurities and metal binders were found to improve the oxidation resistance of TiB<sub>2</sub>, because the rutile scale sinters and becomes dense.<sup>84</sup>

The use of TiB<sub>2</sub> as a component of composites and their oxidation and corrosion behaviors are the subject of a large number of papers. The behavior can be fairly complex because other phases such as aluminum borates become stable and influence the behavior.

### 1.26.9 Ultrahigh Temperature Ceramics

With the realization of the limits of silica-forming ceramics in fast-flowing wet atmospheres, the search for so-called ‘ultrahigh temperature ceramics’ was started. The classes looked at were either the polymer-derived ceramics<sup>85,86</sup> or those forming very refractory oxides, particularly ZrO<sub>2</sub> or HfO<sub>2</sub>. However, the precursor-derived ceramics are silica formers, and therefore at least at temperatures above 1650 °C the problems of silica are inherent. The zirconia and hafnia formers have the problem of fast ionic oxygen transport and thus materials such as ZrB<sub>2</sub> or HfB<sub>2</sub> oxidize extremely fast<sup>87</sup> and are only candidates for very short-lived applications.

Together with the fact of decreasing mechanical properties for all metallic materials at very high temperatures, the only current vision is the development of composites, which are protected from oxidation by some sort of coating. Therefore, environmental barrier systems are a subject of current investigation. The old dream of a carbon-based system with its high temperature properties protected by coatings is still alive and investigated repeatedly with new approaches and systems. It must still be regarded as one of the most promising ways to maintain a strong system at very high temperatures!

## 1.26.10 Refractories

Formed and unformed refractory products have a wide process engineering spectrum of applicability and therefore satisfy various demands and reciprocal actions. The following text will present the corrosion of refractory materials with typical examples of the iron and steel industries. The effecting part-mechanisms can be compared with other industrial sectors and can be divided as follows.

### 1.26.10.1 Chemical Dissolution

The driving force is the existing thermochemical nonequilibrium between the two involved phases (liquid steel/slag/atmosphere – refractory lining) of a system. The thermodynamic stability of a phase (refractory material) is described by the free enthalpy of formation  $\Delta G$  and is heavily affected by the variables of temperature, pressure, and concentration. Besides the dissolution itself, reduction and oxidation processes as well as vaporization and evaporation play essential roles.

### 1.26.10.2 Erosion

The driving force is the flow of melts by gas flushing, vacuum treatment, tapping, and filling the metallurgical reactor respectively, and continuous casting and gases charged with solids. During the first process, a mostly predamaged structure is washed out. During the latter, the damage is affected by solid particles impacting onto the refractory lining because of their inertia, and which break off the material because of surface disruption.

### 1.26.10.3 Mechanical Wear

Thermal shocks and steep temperature gradients (e.g., during heating up, change of temperature when filling a ladle, etc.) cause thermal stresses and sometimes structure changes. Furthermore, the handling in steel plants (e.g., filling a converter with scrap, the cleaning process with skull breakout and removal of slag, the filling and transport of a ladle, etc.) cause wear by mechanical contacts.

These three mechanisms are superimposed and accelerated by infiltration, i.e., weakening the structure of the refractory materials by the ‘inner’ dissolution of the matrix. In practice, chemical dissolution, erosion, mechanical wear, and infiltration appear together with varying degrees of importance.

## 1.26.11 Chemical Dissolution

### 1.26.11.1 Diffusion/Blast Furnace

In a shaft-shaped, double conic built blast furnace, iron ore is constantly reduced to pig iron by carbon and carbon monoxide, respectively. The liquid iron drips into the hearth of the blast furnace, gathers on the ground, and is tapped periodically and in a batch wise manner into transport ladles. The fluid slag in the hearth floating on top of the pig iron fixes the impurities contained in the ore and is extracted continuously.

The hearth, which is water cooled via its outer wall, is lined with carbon and graphite containing bricks. The furnace lifetime is typically 10 years or more with a wall thickness of up to 2 m. In addition to high heat conductivity, another advantage of this lining is the nonwettability of the graphite by slag. No infiltration takes place.

Furthermore, the iron melt approaching from above is saturated with carbon, which strongly decreases attack of the lining. The saturation with carbon is also due to the presence of a bed of coke in the hearth, which is highly porous and filled with slag and pig iron. In addition elements such as Si and Mn accompanying the pig iron decrease the saturation concentration of carbon.<sup>88</sup>

Any iron melt not saturated in carbon causes a linear dissolution rate for a unidirectional water-cooled carbon plate described by the equation:

$$\frac{\Delta x}{\Delta t} = \beta \frac{\rho_{Fe}}{\rho_C} \cdot \frac{C_S - C_0}{100} \quad (\text{cm s}^{-1}) \quad [24]$$

where  $\beta$  is the mass transfer coefficient ( $\text{cm s}^{-1}$ );  $\rho_{Fe}$ , the density of liquid iron ( $6.67 \text{ g cm}^{-3}$ ),  $\rho_C$ , the density of carbon/graphite ( $2.25 \text{ g cm}^{-3}$ );  $C_S$ , the saturation concentration of carbon in liquid iron ( $1500^\circ\text{C}$ : 5.16 wt %);  $C_0$  is the concentration of carbon in liquid iron.

The mass transfer coefficient  $\beta$  is given by

$$\beta = \frac{D_C}{\delta} = \left( \frac{4D_C v}{\pi l_1} \right)^{1/2} \left( \frac{D_C}{v} \right)^{1/6} \quad (\text{cm s}^{-1}) \quad [25]$$

where  $D_C$  is the diffusion coefficient of carbon in liquid iron ( $10^{-4} \text{ cm}^2 \text{ s}^{-1}$ );  $\delta$ , the boundary layer of diffusion (cm);  $v$ , the flow velocity of the melt ( $\text{cm} \cdot \text{s}^{-1}$ );  $l_1$ , the diameter of the convection loop (assumption: 1 cm);  $v$  is the kinematic viscosity of liquid iron ( $10^{-3} \text{ cm}^2 \text{ s}^{-1}$ ).

A laminar flow is predominant (free convection,  $Re \leq 2100$ ) because of low temperature differences at

the phase interface ( $\Delta T < 1$  K). The speed of the convection loop moving at the phase interface can be estimated by using the Reynolds number  $Re$ :

$$v \leq \frac{Re \cdot \nu}{b_1} \quad (\text{cm s}^{-1}) \quad [26]$$

Using the above values, the flow velocity is  $u \leq 21 \text{ cm s}^{-1}$ . Inserting this upper limit in eqn. [25], a mass transfer coefficient  $\beta$  of  $0.035 \text{ cm s}^{-1}$  is obtained. For a temperature of  $1500^\circ\text{C}$ , the carbon concentration in the liquid iron will be  $5.15 \text{ wt } \%$ .<sup>89</sup> Then, eqn. [24] yields the linear dissolution rate:

$$\begin{aligned} \frac{\Delta x}{\Delta t} &= 0.035 \frac{6.67 \cdot 5.16 - 5.15}{2.25 \cdot 100} \\ &= 10^{-5} \text{ cm s}^{-1} \text{ or } 0.04 \text{ cm h}^{-1} \end{aligned} \quad [27]$$

At such a rate, the lining in the hearth of the blast furnace would be fully worn out within a few hours of operation. However, because of the above-described mechanisms, the presence of a coke bed and the decrease in the carbon saturation by the additional elements present in the pig iron, a long service life of up to 2 years is achievable.

### 1.26.11.2 Marangoni Convection/SEN

Preferential wear along the three-phase steel/slag/refractory material interface, such as at a submerged entry nozzle (SEN) used in a mould or in a ladle, can be explained by the temperature and particularly by the concentration-dependent interface phenomenon of Marangoni convection (Figure 5). The refractory material reacts with the steel and the slag. If it contains carbon, it dissolves in the steel which is constrained by the oxide in the refractory material. In turn, the dissolution of the oxide in the refractory material into the slag is constrained by the graphite. Nonetheless,  $\sim 0.1 \text{ wt } \%$  of carbon dissolves into the slag. Because of this reaction, a local concentration gradient develops at the steel/slag interface. For

Figure 5 Advanced wear by Marangoni convection.

carbon-containing refractory material, there is a slightly increased carbon concentration in the region close to the three-phase interface, which makes the interfacial tension  $\sigma_{II}$  (Figure 5) higher than  $\sigma_I$ . A part of the carbon dissolved in the slag reacts with the steel, thereby forming carbon monoxide (CO) and this causes a locally decreased oxygen content at point II. The corresponding increase in the interfacial tension decreases the capillary activity of the slag and the steel tends to convect from point I to point II in order to decrease the interfacial tension there.

In a lot of cases, no infiltration occurs, because the corrosion progress is faster than the speed of infiltration. To estimate the extent of corrosive wear, one may use the approximation of eqn. [24]. The mass transfer coefficient  $\beta$  is estimated well by eqn. [25]. The flow velocity of the steel and slag along the phase interface is then<sup>90</sup>:

$$v_M = -\frac{b_g}{4\eta_s} \left( \frac{d\sigma}{dC} \text{grad } C + \frac{d\sigma}{dT} \text{grad } T \right) \quad (\text{cm s}^{-1}) \quad [28]$$

where  $b_g$  is the characteristic length of the corrosion groove (assumption:  $1 \text{ cm}$ ) and  $\eta_s$  is the dynamic viscosity of steel ( $1600^\circ\text{C}$ :  $0.04 \text{ g cm}^{-1} \text{ s}^{-1}$ ).

In this equation, the change in the interfacial energy of the steel/slag interface in relation to the oxygen content in the liquid steel is estimated as

$$\frac{d\sigma}{dC} = -\frac{200}{C_{[O]}^I} [\text{mN m}^{-1} \text{ wt } \%^{-1}] \quad [29]$$

the approximated concentration gradient of the oxygen along the phase interface is

$$\text{grad } C = \frac{C_{[O]}^I - C_{[O]}^{II}}{b_g} = 0.001 \text{ wt } \% \text{ cm}^{-1} \quad [30]$$

the change in the interfacial energy in relation to the temperature is<sup>91</sup>

$$\frac{d\sigma}{dT} = \sigma_T = -0.2 \text{ mN m}^{-1} \text{ K}^{-1} \quad [31]$$

and the approximated temperature gradient because of the heat removal to the refractory material is

$$\text{grad } T = \frac{T^I - T^{II}}{b} = 10 \text{ K cm}^{-1} \quad [32]$$

With an assumed oxygen content  $C_{[O]}^I = 0.004 \text{ wt } \%$  (40 ppm) in eqn. [19], the insertion of the values from eqns. [30]–[32] into eqn. [28] yields a flow velocity  $v_M$  of  $325 \text{ cm s}^{-1}$ .

Assuming that the back-flow velocity along the refractory material/slag interface is about the same

as  $v_M$ , the thickness of Prandtl's flow-boundary-layer  $\delta_{Pr}$  can be easily calculated:

$$\delta_{BL} = \left( \frac{\eta_{Sl} \cdot b}{\rho_{Sl} \cdot u_M} \right)^{1/2} \quad (\text{cm}) \quad [33]$$

where  $\eta_{Sl}$  is the dynamic viscosity of the slag ( $2 \text{ g cm}^{-1} \text{ s}^{-1}$ ,  $0.2 \text{ Pa s}^{-1}$ ) and  $\rho_{Sl}$  is the density of the slag ( $2.7 \text{ g cm}^{-3}$ ).

The thickness of the Nernst's diffusion-boundary-layer  $\delta_N$  is then

$$\delta_N = \left( \frac{\eta_{Sl}}{\rho_{Sl} D_{Sl}} \right)^{-1/3} \delta_{Pr} \quad (\text{cm}) \quad [34]$$

where  $D_{Sl}$  is the diffusion coefficient of the corrosion determining component ( $1650^\circ\text{C}$ :  $1 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ )

With these material values, we get  $\delta_{Pr} = 1.51 \times 10^{-2} \text{ cm}$  and  $\delta_N i = 1.67 \times 10^{-4} \text{ cm}$ . Accordingly, the mass transfer coefficient  $\beta$  is calculated by

$$\beta = \frac{D_{Sl}}{\delta_N} \quad (\text{cm s}^{-1}) \quad [35]$$

The result is  $\beta = 6 \times 10^{-4} \text{ cm s}$ . Assuming a slag whose starting content of  $\text{Al}_2\text{O}_3$  is  $\sim 13 \text{ wt } \%$ , and whose saturation concentration at  $1650^\circ\text{C}$  is in the range of  $60 \text{ wt } \%$   $\text{Al}_2\text{O}_3$ , the wear of a corundum-enriched, graphite-containing refractory material ( $\rho_R = 3.3 \text{ g cm}^{-3}$ ) due to Marangoni convection approximately amounts to

$$\begin{aligned} v_{\text{corr}} &= 360 \times 6 \times 10^{-4} \frac{2.7}{3.3} (60 - 12) \\ &= 8.5 \text{ mm h}^{-1} \end{aligned} \quad [36]$$

which is in accordance with laboratory experiments. The question is how to decrease this extremely severe corrosion. The process cannot be influenced easily. In the case of the continuous casting process, the concentration gradient and the temperature gradient are nearly fixed. The temperature and concentration dependency of the interfacial energy are natural values, and the same applies for the dynamic viscosity of the steel. Therefore, the only way left is to use a refractory material that is as chemically inert as possible.

This is, for instance, achieved by the implementation of a sleeve made of  $\text{ZrO}_2$  at the three-phase interface of a SEN. According to eqn. [24], the slag and the mould powder, respectively, can be enriched with  $\text{Al}_2\text{O}_3$  up to a certain amount, in order to maintain the difference in the saturation concentration as small as possible.

### 1.26.11.3 Oxidation/Ladle

The crude steel coming from the melting aggregates (converter or electric arc furnace) is partially already post-treated during tapping into the ladle and then again within the ladle. This treatment, which is referred to as secondary metallurgy, includes the process steps<sup>92</sup> of degassing, decarburization, desulphurization, dephosphorization as well as removal of trace elements, fine adjustment of alloying contents, deoxidization, inclusion transformation, improvement in the purity levels as well as the solidifying structure, adjustment and homogenization of temperature and chemical composition.

To minimize the thermal stresses and the corresponding wear because of the actual temperature gradient when filling with crude steel ( $T$  up to  $1800^\circ\text{C}$ ), the cold ladle lined with  $\text{MgO-C}$  bricks is preheated for 2 hours in the steel mill. A newly lined ladle does not have a slag layer protecting the bricks against oxidation of the binding carbon (graphite, 5–15 wt %). As an instantaneous result of this pre-heating procedure, the graphite oxidizes. The carbon bonding and its advantageous properties such as the good thermal shock resistance and the nonwettability by slag are lost. At the same time, an enormous pore volume (about 35 vol %) is opened. Steel and slag can easily infiltrate into the microstructure and therewith lead to 'inner' dissolution.

The temporal progress of the reaction

in a  $\text{MgO-C}$  brick can be described by the following differential equation:

$$\frac{dx_i}{dt} = -2V_C D_P \frac{n_0 - n_i}{x_0 - x_i} \quad [38]$$

The sharp transition from the bright, decarburized outer zone to the black core suggests a topochemical reaction which is controlled by diffusion ( $\sqrt{t}$ -law). The determining factor is the pore-diffusion coefficient  $D_P$ <sup>93</sup>

$$D_P = D_{\text{O}_2} \gamma p_c \quad (\text{cm}^2 \text{ h}^{-1}) \quad [39]$$

with

$$D_{\text{O}_2} = 2.7 \times 10^{-2} T^{1.79} \quad (\text{cm}^2 \text{ h}^{-1}) \quad [40]$$

and

$$\gamma = 1.84 \times \sqrt{p_c} - 0.3 \quad [41]$$

where  $D_{O_2}$  is the diffusion coefficient of oxygen;  $T$ , the temperature ( $\approx 1373$  K);  $\gamma$ , the labyrinth factor; and  $p_c$  is the open porosity of the decarburized zone ( $\approx 0.35$ ).

The insertion of these values results in  $D_p = 3081 \text{ cm}^2 \text{ h}^{-1}$ . The solution of the differential equation [38] for an infinite plate is given by<sup>14</sup>

$$(1 - \phi)^2 = \tau \quad [42]$$

with

$$\phi = \frac{x_i}{x_0} \quad (x_i = x_0 \text{ at } t = 0) \quad [43]$$

where  $x_i$  is the position of the reaction front in the plate (cm) and  $x_0$  is the total thickness of the plate (cm).

$$\tau = \frac{t}{t_0} \quad [44]$$

where  $t$  is the time (h) and  $t_0$  is the time for total decarburization of a plate with  $x_0$  (h) and

$$t_0 = \frac{x_0^2}{2zV_C D_p (n_0 - n_i)} \quad (\text{h}) \quad [45]$$

where  $V_C$  is the mole volume of graphite ( $5 \text{ cm}^3 \text{ mol}^{-1}$ ),  $z$ , the geometry factor (infinite plate:  $z = 2$ );  $n_0$ , the oxygen content at the plate surface (20 vol %;  $2 \times 10^{-6} \text{ mol cm}^{-3}$ ); and  $n_i$  is the oxygen content at the reaction front ( $n_i \ll n_0$ ,  $n_i \rightarrow 0$ ).

A MgO–C brick with  $x_0 = 10 \text{ cm}$  would be totally decarburized within  $t_0 = 1014 \text{ h}$ . The time  $t$  required to decarburize 1 cm ( $x_i = 9 \text{ cm}$ ) of the brick results as follows:

$$\tau = \left(1 - \frac{9}{10}\right)^2 = 0.01 \quad [46]$$

$$\text{with } t = \tau t_0 = 0.01 \times 1014 \text{ h} = 10.14 \text{ h}$$

Numerous experiments demonstrated that the process is in fact controlled by diffusion and is extensively blocked by specific additives, such as  $>10 \text{ wt } \% \text{ ZrB}_2$ . However, the addition of 3 wt % metallic aluminum as an antioxidant has hardly any effect, since the porosity of the decarburized refractory material is high, and during the coke reaction at  $T \geq 800^\circ \text{C}$ , the metallic aluminum is consumed by the formation of  $\text{Al}_3\text{C}_4$ , and above  $1200^\circ \text{C}$  by spinel formation.

## 1.26.12 Erosion

### 1.26.12.1 Blast Wear/Pipes

Pneumatic conveying systems and pipes in thermo-technical aggregates are subject to severe wear

because of erosion. The reason for this is the segregation of a solid loaded gas flow because of the mass inertia of its solid particles. These particles impact mostly in areas of flow redirection (elbow) onto the refractory lining, whereby a cyclic mechanical stress occurs at permanently changing surface areas. For brittle materials, such as refractories, these alternating local impacts and corresponding multiaxial tensile and compression loads finally cause material removal by surface disruption. It should be noted that the resulting wear is always a system characteristic and is influenced by numerous factors.

At room temperature, the testing of refractory materials with respect to their wear by perpendicular impacting solid particles is performed according to ASTM C 704. For this purpose, 1000 g of SiC particles of predefined granularity are accelerated by a pressurized air flow within  $450 \pm 15 \text{ s}$  and shot over a distance of 203 mm perpendicular onto a surface of a test sample. The resulting wear volume (in  $\text{cm}^3$ ) is determined by weighing the geometrically well-defined sample.

However, the results thus achieved can hardly be transferred to the temperatures applied in operation. That is why a special experimental setup was developed, which is as far as possible in accordance with ASTM C 704 and whereby the wear by impacting particles can be determined at temperatures of up to  $1400^\circ \text{C}$ . The main item of this experimental setup is a ring burner by which the pressurized air flow, the blasting abrasive (SiC particles), and the test sample are heated to the relevant test temperature. It has been shown that the wear volume of heterogenic refractory materials decreases with an increase in temperature, which correlates quite well with the change in thermomechanical properties.

While brittle–elastic deformation behavior occurs at room temperature, viscoplastic deformation behavior is dominant at high temperatures, where molten phases from the binder phase are present. The local stress peaks, which are generated by the impacting SiC particles, are decreased by plastic deformation and by stress relaxation of the binder phase, respectively. In this context, particularly wear-resistant grains (SiC, corundum) incorporated inside the microstructure show no wear-reducing action.<sup>94</sup> Moreover, these grains break upon impact of a SiC particle because of their poor ductility.

### 1.26.12.2 Flowing Melts/Converter

During filling of a torpedo ladle or a converter with pig iron, or of a ladle with crude steel, the melt often ‘falls’ at about 2 m. Because of the high flow speed, the lining in the collision area of the melt

stream, which is possibly predamaged by chemical dissolution, thermal shock stress, or infiltration, is washed out. However, a quantitative prognosis is not possible. The same applies for the circulation current generated during gas stirring treatment within a converter or in a ladle. In connection with the high flow velocities of the melt, cavitation erosion might play a significant role, but this has not been examined further in the field of steel production.

## 1.26.13 Mechanical Wear

### 1.26.13.1 Thermal Shock Resistance/Ladle

In practice, mechanical wear as an instantaneous result of a poor thermal shock resistance is commonly found. During the filling of a ladle with crude steel, the lining is heated up rapidly from 1000 to 1800 °C within a few minutes. High tensile stresses develop in the surface, which frequently results in a single incipient crack, which can grow catastrophically. Off-bursts occur in the surface region of the lining, which is also referred to as 'spalling.' This mechanism is promoted by a modified structure of surface areas containing slag infiltrations.

An assessment of various refractory materials concerning their thermal shock resistance can be performed by the quick quenching of a 950 °C test sample by blowing pressurized air (DIN EN V 993-11) onto its surface, or by dipping the test sample into water (DIN 51068-1). Then tensile stresses occur, starting from the surface, which result in a large amount of incipient cracking. Usually, a catastrophic break does not occur.

No isothermal boundary conditions can be found in these cases and therefore a theoretical treatment becomes difficult. Modeling of 'quasistationary' crack propagation is possible, but during rapid heating up of a ladle lining, unstable crack propagation occurs. Therefore, characterization of the thermal shock resistance of refractory materials uses the resistance parameter  $R$  during unstable crack propagation and  $R_{st}$  during stationary crack propagation<sup>95</sup>:

$$R''' = \frac{G_F E}{\sigma_c^2} \approx L \text{ (mm)} \quad [47]$$

$$R_{st} = \sqrt{\frac{G_F}{\alpha^2 E}} \text{ (m}^{1/2} \text{ K)} \quad [48]$$

where  $G_F$  is the crack energy (J m<sup>-2</sup>);  $E$ , the modulus of elasticity (GPa);  $\sigma_c$ , the critical stress (MPa);  $\alpha$ , the thermal expansion coefficient (K<sup>-1</sup>); and  $L$  is the characteristic length (mm).

Both equations were derived from nonlinear fracture mechanics, which is necessary when dealing with refractory materials, since they have a very heterogeneous structure (grains, binder phase, pores). Together, both crack resistance parameters describe the so-called structure flexibility. From eqns. [47] and [48], it is plain that an increase in the required crack energy and the crack propagation work  $G_F$  with both unstable as well as 'quasistationary' crack propagation is advantageous in order to reach a high value for the respective resistance parameter and, therefore, to achieve a high thermal shock resistance.

This can be obtained in structures with coarse grains in a fine-grained matrix, where entanglement of the grains increases the crack length. The modulus of elasticity, however, has the opposite effect, which is dependent on the mechanism of the crack propagation alone. With unstable crack propagation, the crack itself and the incipient crack arising must be as big as possible to reach the area of the 'quasistationary' crack propagation without reaching the catastrophic breakpoint. In the area of the stationary crack propagation, the modulus of elasticity should be as small as possible, which calls for an optimization of the structure concerning both crack propagation mechanisms. A crack then gradually propagates with every higher and more critical temperature difference.

In spite of great experimental endeavor, no definite connection between the resistance parameters and the standard tests for judging the thermal shock resistance has been found.<sup>96</sup> At the moment, values must be inserted into the aforementioned equations, which have been measured isothermally.

Critical heating rates may be calculated according to the example of a hot plate made out of sintered corundum (99% Al<sub>2</sub>O<sub>3</sub>) at 1000 °C:

$$\dot{T} = \frac{\varepsilon_c (1 - 2\mu)}{3\alpha} \frac{16a}{x^2} \text{ (K s}^{-1}\text{)} \quad [49]$$

where  $\varepsilon_c$  is the critical elongation (0.001);  $\mu$ , the Poisson ratio (0.21);  $\alpha$ , the thermal expansion coefficient ( $1 \times 10^{-5}$  K<sup>-1</sup>);  $a$ , the thermal diffusivity ( $1 \times 10^{-6}$  m<sup>2</sup> s<sup>-1</sup>); and  $x$  is the thickness of the plate (0.02 m).

Inserting the values results in  $\dot{T} = 0.77$  K s<sup>-1</sup>. If the sample cools down/warms up faster, a breakage (crack) occurs.

### 1.26.13.2 Carbon Bursting/Blast Furnace

In industrial processes (chemical plants, blast furnace shaft) in the temperature range from 400 to 800 °C,

carbon bursting of refractory material in atmospheres containing CO is known. This phenomenon is due to the temperature dependence of the Boudouard equilibrium:

When crystalline graphite precipitates in refractory materials, it can create an enormous crystallization pressure, capable of bursting the structure. This precipitation is said to be catalytically promoted by metallic iron, hematite ( $\text{Fe}_2\text{O}_3$ ), and magnetite ( $\text{Fe}_3\text{O}_4$ ). In examination of the resistance to CO according to ASTM C 288, refractory materials are exposed to a pure CO atmosphere after a thermal pretreatment at 500 °C for 200 h.

A small amount of hydrogen ( $\sim 3\%$ ) accelerates the carbon precipitation and thus we assume a catalytic effect of hydrogen. After the test, a visual evaluation of the refractory material leading to a classification concerning its resistance to CO is performed. The resulting crystallization pressure ( $\pi - 1$ ) can be calculated using the following equation:

$$\pi - 1 = \frac{-\Delta G^0 - RT \ln K_C}{\Delta V_C \frac{R}{R^*}} \quad [51]$$

where  $\Delta G^0$  is the free enthalpy in the standard state (J/mol);  $R$ , the universal gas constant ( $8.314 \text{ J mol}^{-1} \text{ K}^{-1}$ );  $R^*$ , the gas constant ( $84.8 \text{ atm cm}^3 \text{ mol}^{-1} \text{ K}^{-1}$ );  $T$ , the temperature (K);  $K_C$ , the equilibrium constant; and  $\Delta V_C$  is the mole volume of graphite ( $5 \text{ cm}^3 \text{ mol}^{-1}$ ).

At 500 °C (773 K), magnetite is reduced to metallic iron, if the volumetric contents of CO and  $\text{CO}_2$  are equal; the formation of graphite results for the earlier stated reaction [50] with

$$K = \frac{P_{\text{CO}_2}}{P_{\text{CO}}} = 2 \quad \text{with } a_C = 1 \quad [52]$$

$$\begin{aligned} \Delta G^0 &= 169452 - 172.6T, \\ \Delta G^0(773\text{K}) &= -35522 \text{ J mol}^{-1} \end{aligned} \quad [53]$$

Inserting all values in eqn. [51] results in a crystallization pressure of 63 375.3 atm, corresponding to 62 150 bars, thereby destroying the structure of the refractory material.

### 1.26.13.3 Destruction due to Impact/Converter

In the converter, crude steel is produced by blowing oxygen onto and/or into the molten pig iron. In this

process, the dissolved carbon is oxidized to a certain amount. Iron and those elements accompanying the pig iron such as P, Si, and Mn are oxidized and form a slag. Temperatures of above 2000 °C are reached by strong exothermal reactions. It is, therefore, preferable that a large part of the crude steel charge is replaced by scrap steel, whose melting offers a cooling effect for the melt.

The lining of an emptied converter is  $\sim 1200$  °C at the hot bottom and is therefore under both thermal and mechanical stresses upon refilling with scrap steel.

To estimate the procedures during charging, the transmitted mechanical energy of a falling scrap piece  $mgb$  onto an impact area  $A$  is equated with the required crack energy  $nG_F$  for a number of  $n$  cracks. The prevailing impact area and the number of produced cracks are unknown, since the position of the scrap piece at the moment of impact is incidental and the shock wave spreads into the floor. It is assumed that a scrap piece falling from a height  $b = 4$  m with a mass  $m = 100$  kg influences a surface area  $A = 0.1 \text{ m}^2$ . The measured crack energy of the MgO–C material at 1200 °C is  $G_F = 500 \text{ J m}^{-2}$ . The number of emerging cracks is

$$n = \frac{mgb}{AG_F} = \frac{100 \times 9.81 \times 4}{0.1 \times 500} \approx 80 \quad [54]$$

and accordingly MgO–C material may break out of the surface. In the following refining process, temperatures of above 1800 °C develop, so there is also a good chance that cracks will heal again. To improve the structural flexibility of such stressed components, metallic aluminum powder and steel needles are added to the MgO–C material.<sup>97</sup>

## 1.26.14 Infiltration by Steel and Slag

### 1.26.14.1 Basic Equations

The contact of a pure oxide and a graphite-containing refractory material with liquid steel or slag in a thermodynamic equilibrium is described by wetting theory. The vectors of the surface tensions of the three involved phases acting at the point of contact of all three phases are in a mechanical equilibrium state:

$$\sigma_R - \sigma_S \cos \theta - \sigma_{R/S} = 0 \quad [55]$$

where  $\sigma_R$  is the surface tension of the refractory material ( $\text{mN m}^{-1}$ );  $\sigma_S$ , the surface tension of the

steel or slag ( $\text{mN m}^{-1}$ );  $\sigma_{\text{R/S}}$ , the interfacial tension between refractory material/steel or refractory material/slag ( $\text{mN m}^{-1}$ ); and  $\theta$  is the wetting angle ( $^\circ$ ).

The interactions of the three phases involved are characterized by the wetting angle of contact:

$$\cos\theta = \frac{\sigma_{\text{R}} - \sigma_{\text{R/S}}}{\sigma_{\text{S}}} \quad [56]$$

and

$$\theta > 90, \quad \text{if } \sigma_{\text{R}} - \sigma_{\text{R/S}} < 0 \text{ (non-wettability)}$$

$$\theta = 90, \quad \text{if } \sigma_{\text{R}} - \sigma_{\text{R/S}} = 0$$

$$\theta < 90, \quad \text{if } \sigma_{\text{R}} - \sigma_{\text{R/S}} > 0 \text{ (wettability)}$$

The wetting angle of contact  $\theta$  and the surface tension  $\sigma_{\text{S}}$  are the decisive values for the infiltration of a capillary or pore by steel or slag, which can be determined experimentally. The equilibrium of forces in a partly filled pore is then:

$$\rho_{\text{S}} g b = - \frac{4\sigma_{\text{S}} \cos\theta}{d} \quad [57]$$

where  $\rho_{\text{S}}$  is the density steel/slag ( $\text{kg m}^{-3}$ );  $g$ , the acceleration of gravity ( $\text{m s}^{-2}$ );  $b$ , the height of steel-/slag-column above the pore entry (m);  $d$  is the pore diameter (m).

If the wetting angle of contact  $\theta$  is smaller than  $90^\circ$ , capillary ascension is present. For instance, a liquid slag penetrates the pore or capillary system of an oxidic refractory material without the effect of any external force. In the case of liquid steel and oxide refractory material, capillary depression is present, since the wetting angle of contact is  $\theta > 90^\circ$ . Thus, an external (ferrostatic) pressure is necessary to allow the liquid steel to penetrate into the pore or capillary system. The same is true for a slag that does not wet the graphite binder phase of the oxide refractory material.

The infiltration speed of the slag or steel into the structure results from the Hagen–Poiseuille equation<sup>98</sup>:

$$\frac{dl}{dt} = \frac{d^2}{32\eta l} \left( \frac{4\sigma_{\text{S}} \cos\theta}{d} + \rho g b \right) \quad [58]$$

Integration leads to the penetration depth  $l$ , in relation to the time  $t$ :

$$l = \sqrt{\left( \frac{d\sigma_{\text{S}} \cos\theta}{4\eta_{\text{S}}} + \frac{d^2 \rho_{\text{S}} g b}{16\eta_{\text{S}}} \right) t} \quad [59]$$

where  $l$  is the penetration depth (m);  $\eta_{\text{S}}$ , the dynamic viscosity of steel/slag (Pa s); and  $t$  is the time (s).

## 1.26.15 Examples

### 1.26.15.1 Slag/MgO

A MgO brick in contact with a slag with a minimal surface energy at  $1600^\circ\text{C}$  ( $\sigma_{\text{S}} = 0.51 \text{ N m}^{-1}$ ,  $\eta_{\text{S}} = 1 \text{ Pa s}$ ) will show a penetration depth of 1 cm within a pore  $d = 50 \mu\text{m}$  according to eqn. [59] after an interaction period of 10 min. The dependence on the wetting angle disregarding a slag-column above the pore entry is outlined in Table 1. Note that this estimation is obtained with simplifications, namely that there is neither chemical interaction between the slag and the refractory material nor a temperature gradient within the inner structure.

### 1.26.15.2 Steel/MgO

Liquid steel ( $1600^\circ\text{C}$ :  $\sigma_{\text{S}} = 1.5 \text{ N m}^{-1}$ ,  $\eta_{\text{S}} = 6.8 \times 10^{-3} \text{ Pa s}$ ,  $\rho_{\text{S}} = 7.700 \text{ kg m}^{-3}$ ) and a MgO brick show completely different infiltration because of the wetting angle of  $\theta = 120^\circ$ . According to eqn. [57], steel can only penetrate into open pores, if their diameter is sufficiently large. For this, Table 2 gives the infiltration

**Table 1** Penetration depth of a slag in relation to the wetting angle of contact ( $d = 50 \mu\text{m}$  and  $t = 600 \text{ s}$ )

$(^\circ)$	$l \text{ (cm)}$
0	1.96
10	1.94
20	1.90
30	1.82
40	1.71
50	1.57
60	1.38
70	1.14
80	0.81
89	0.26
90	0

**Table 2** Infiltratable pore diameter  $d$  and penetration depth  $l$  in relation to the steel pool depth  $h$

$h \text{ (m)}$	$d \text{ (m)}$	$l \text{ (m). } d = 200 \text{ m}$
0.25	172	0.73
0.50	86	2.10
0.75	57	2.80
1.00	43	3.48
1.25	34	4.00
1.50	29	4.46
1.75	25	4.87
2.00	22	5.25
2.25	19	5.61
2.50	17	5.94
2.75	16	6.26
3.00	14	6.56

pore diameter  $d$  in relation to the depth of the steel pool,  $b$  (ferrostatic pressure). As we can see, the greater the depth, the higher the risk of infiltration of smaller pores.

Considering a depth,  $b$ , the penetration depth of the steel into a pore having a diameter of  $d = 200 \mu\text{m}$  after 10 min is calculated according to eqn. [59]. The penetration depth increases with a growing pool depth  $b$  and amounts to  $a$  about 2 m (see Table 2).

### 1.26.15.3 Steel/MgO–C

The graphitic binder phase of MgO–C bricks is resistant to slag because graphite is not wetted and only minimally dissolved. In contact with liquid steel, the situation is different. For example, carbon is soluble in iron at a temperature of  $1600^\circ\text{C}$ , up to 5.41 wt %. Therefore MgO–C should not be useful in practice and the question arises: ‘Why can MgO–C be used?’

1. From the Vatcher–Hamilton equilibrium between dissolved oxygen in iron and carbon<sup>88</sup>:

At  $1600^\circ\text{C}$  the partial pressure  $P_{\text{CO}}$  is

$$\underline{\text{C}} \cdot \underline{\text{O}} = 0.0024 P_{\text{CO}} \quad [61]$$

If a steel melt with a dissolved oxygen content of 30 ppm tries to enter into a pore and therefore comes into contact with the graphitic binder phase, the carbon activity  $a_{\text{C}}$  at this specific point is, thus, 1. Inserted into eqn. [45]

$$P_{\text{CO}} = \frac{1 \times 0.003}{0.0024} = 1.25 \text{ bar} \quad [62]$$

At the contact point, therefore, CO gas is produced, which separates the reaction partners from each other and retards the dissolution and the infiltration kinetically.

2. If steel would enter into the pore despite the CO cushion, the solubility of the carbon would be strongly decreased. The partial pressure  $P_{\text{CO}}$  inside the structure is only 0.05 bar. From eqn. [61], we have  $\underline{\text{C}} = 0.04 \text{ wt } \%$  for the dissolved carbon, which can be supported by experimental data.<sup>99</sup>

3. Furthermore, the formation of a MgO protective layer may take place because of the carbothermal reaction inside the structure:

Gaseous magnesium dissolves in the steel and reacts with the oxygen also dissolved in the steel in

order to form secondary MgO that precipitates at the interface (heterogeneous nucleation) and, thus, restrains further infiltration into the structure.

4. The carbon solubility in liquid iron is also affected by higher aluminum levels and the reaction thereof with oxygen. If the MgO–C material contains, for instance, metallic aluminum as an antioxidant, this metallic aluminum melts on contact with the steel and dissolves into the steel, infiltrating the open pores. During this process, an oxidation reaction according to the following equation occurs:

The equilibrium constant  $K$  of this reaction at  $1600^\circ\text{C}$  is

$$K = \frac{\underline{\text{Al}}^2 \cdot \underline{\text{O}}^3}{1} = e^{-\Delta G^0/RT} = 3 \times 10^{-13} \quad [65]$$

In general, the steel penetrating the pores contains 0.1 wt % of dissolved aluminum. The content of dissolved oxygen then in the equilibrium state is, according to eqn. [65],  $\sim 3 \text{ ppm}$ . As a consequence, the oxygen potential is decreased so that the bumping effect of the CO gas and the formation of a MgO protective layer are suspended. The infiltration and dissolution of the graphitic binder material are promoted. Accordingly, the content of carbon dissolved in the infiltrate, from eqn. [61], is

$$\underline{\text{C}} = \frac{0.0024 \times 0.05}{0.0003} = 0.4 \text{ wt } \% \quad [66]$$

which is much less than 5.4%.

In summary, infiltration influences the corrosion profoundly. It may have beneficial effects, if the reaction with the refractory material leads to a surface compaction (formation of an MgO protective layer) or to stiffening of the infiltrate (slag), but it also can have detrimental effects, if chipping (spalling) occurs.

### 1.26.16 Concluding Remarks

As can be seen from this chapter about ceramics and refractories, the subject is fairly complex, because often the interplay of physical boundary conditions and chemical interaction is governing corrosion processes. Furthermore, the microstructure of the materials, particularly when it comes to refractories, is likewise adding complexity, because several phases interact simultaneously and the ubiquitous porosity is

also causing problems in investigating the processes. Thus, despite its industrial importance there are a lot of things to be learned and certainly there are good possibilities to improve the corrosion resistance.

We are sure that the progress, which was made in the investigations of the technical ceramics and is described in the first parts of this chapter, will help both to extend the use of those materials in high temperature processes and to find economic viable solutions for the refractory world. Doing so could become a key issue in helping us to work more efficiently and less harmfully for our environment in many processes. The efforts to protect our climate could have a significant input from the work on corrosion resistant ceramics and refractories.

## Symbols

$C_b$	Critical Al content of metal at breakaway oxidation, nominal or average
$C_{bi}$	Critical Al content at breakaway oxidation at the metal-oxide interface
$C_{min}$	Minimum initial Al content needed for alumina formation
$C_o$	Initial Al content
$d$	Specimen thickness
$D_{Al}$	Self-diffusion coefficient of aluminum
$D_o$	Self-diffusion coefficient of oxygen
$E_{ox}$	Elastic modulus of oxide
$M$	Metal: Fe, Ni or Co
$p'_{O_2}$	Partial pressure of oxygen at the metal-oxide interface, Al/Al <sub>2</sub> O <sub>3</sub> equilibrium
$p''_{O_2}$	Partial pressure of oxygen at the oxide-gas interface
$t_b$	Exposure time to breakaway oxidation
$t_z$	Exposure time to zero mass gain
$W^*$	Strain energy
$W_{ad}$	Work of adhesion
$[X]$	Concentration of element X, atom percent
$\alpha$	Coefficient of thermal expansion
$\gamma_{int}$	Surface energy of the metal-oxide interface
$\gamma_{met}$	Surface energy of the metal substrate
$\gamma_{ox}$	Surface energy of the oxide scale
$\rho$	Alloy density
$\nu$	Poisson's ratio
$\xi$	Scale thickness
$\xi_f$	Critical scale thickness at scale spallation
$\Delta\alpha$	Change in coefficient of thermal expansion
$\Delta T$	Change in temperature

## 1.24.1 Introduction

This chapter will discuss the oxidation behavior of alumina-forming alloys, particularly MCrAl and M(Al) where M is Fe, Ni and to a lesser extent, Co. (Information on intermetallic aluminides, such as NiAl, TiAl, or Fe<sub>3</sub>Al is included in **Chapter 1.25, High Temperature Corrosion of Intermetallic Alloys**) For the most part, these alloys owe their high temperature oxidation resistance to the formation of a dense, protective, external alumina scale; although some portion of the discussion will concern alloys that benefit from Al additions but do not exclusively form alumina scales. Compositions generally will be discussed in atomic percentage, with Al contents typically  $\leq 22\%$  in the binary

alloys. However, in **Table 1**, commercial alloy compositions are given in weight or mass percentage, which is the common convention, while **Table 2** provides compositions in atomic percentage. The oxidation behavior of alumina-forming alloys will be discussed in a general sense in **Sections 1.24.2–1.24.5** for air or oxygen environments. **Section 1.24.6** covers the behavior of these materials in different oxidants, for example, H<sub>2</sub>O, S, C, or N. This discussion assumes some basic knowledge of the high temperature oxidation concepts that were discussed in **Chapter 1.10, Oxidation of Metals and Alloys**. The terminology is defined in the Glossary. It is almost impossible to discuss the oxidation behavior of alumina-forming alloys without discussing the reactive element (RE) effect.<sup>1–11</sup> Low levels ( $\sim 0.1$  at.%) of RE dopants have a dramatic effect on oxidation performance and most commercial alloys contain one or more additions. The examples given will rely heavily on the oxidation database of the Corrosion Science and Technology Group in the Materials Science and Technology Division at Oak Ridge National Laboratory (ORNL) in Oak Ridge, TN.<sup>12</sup>

### 1.24.1.1 Functionality of Alumina-Forming Alloys

In a general sense, applications for alumina-forming alloys are only for the highest temperatures ( $>900^\circ\text{C}$ ) or most aggressive conditions. At lower temperatures, chromia-forming alloys, such as stainless steels, usually have sufficient high temperature oxidation resistance for most applications. In fact, Ni–Cr alloys are often discussed for applications as high as  $1200^\circ\text{C}$ .<sup>13</sup> However, metal consumption rates for Fe- and Ni-based chromia forming alloys become significant at temperatures above  $1000^\circ\text{C}$ .<sup>14</sup> These differences are not apparent at short intervals, but become more important after long intervals. **Figure 1** shows the total mass gain and the spalled mass of alloy coupons after 15 kh at  $1000^\circ\text{C}$  in laboratory air. (Total mass gain (i.e., specimen mass gain + spalled oxide) will be frequently used in this chapter as it is directly proportional to metal wastage and gives more information than just the specimen mass change which is typically lower than the total mass. Total mass is obtained by conducting the exposure in a preannealed alumina crucible.<sup>15</sup> The spalled mass can be larger than the total mass because the spalled mass includes the metal cations while the total mass reflects only O uptake.) One of the most

oxidation-resistant, commercial, chromia-forming alloys is the Ni-based, alloy 230, [Table 1](#). Even after 15 kh at 1000 °C (although there were only scale spallation-inducing, thermal cycles every 500 h, see [Section 1.24.4.4.6](#)), the mass gain for alumina-forming alloys (e.g., 214, MA956, PM2000, see [Table 1](#)) is not significantly lower than that for alloy 230. However, the amount of spalled oxide for the alumina-forming alloys is typically much lower ([Figure 1](#)). This has significant implications for extrapolations of oxidation-limited lifetimes for real applications where 40 kh is often considered a short interval between equipment overhauls and fossil or nuclear energy plant life can be 300 kh.<sup>16</sup> Also, alloy 230 was one of the best commercial alloys tested in the study. A number of chromia-forming alloys, particularly those without a RE addition (e.g., 330RA and 800H, while 230 contains La, [Table 1](#)) showed significantly more metal wastage in the study and a few had to be stopped early because of the degree of attack.

Above 1000 °C, the benefit of alumina-forming alloys becomes much more evident. Instead of just comparing the mass change of various alloys, consider the example of designing a heat exchanger where the wall thickness will determine the lifetime of the component. [Figure 2](#) shows the time to reach 20–40 mg cm<sup>-2</sup> total mass gains as a function of specimen thickness for alloy 230 (Ni–Cr, [Table 1](#)) at 1100 °C in laboratory air (exposed with 100 h per cycle). These times are compared with the times to breakaway oxidation ( $t_b$ , see [Section 1.24.5](#)) for oxide dispersed FeCrAl alloy MA956. As will be discussed in [Section 1.24.5](#), Ni-based alloys do not have such a definitive, binary-like, transition time and instead show an increase in the rates of mass gain and spallation. Thus, for a 2 mm thick alloy 230 specimen, almost 7 kh of exposure at 1100 °C was needed to reach 20 mg cm<sup>-2</sup> of total mass gain but in less than 1000 h more exposure, the mass gain increased to 40 mg cm<sup>-2</sup> ([Figure 2](#)). These times were not significantly different

for alloy 230 specimens that were <1 mm thick. In contrast, a drastic increase in the time to breakaway oxidation was observed for MA956 coupons in this exposure. The example of MA956 is given because a number of other alloys (typically with higher Al contents) have such high values for  $t_b$  that it is difficult to put them on the same plot with alloy 230.<sup>14</sup> It is easy to see that if one were designing a 1100 °C heat exchanger

with a minimum lifetime service of 25 kh it would be extremely difficult to predict any wall thickness of alloy 230 that would be applicable but an extrapolation of the MA956 data would suggest a minimum wall thickness of ~3 mm. Oxidation-limited lifetime predictions are further discussed in [Section 1.24.5](#).

The upper temperature limit for alumina-forming alloys is, of course, application dependent.

**Figure 1** Bar graph of the total mass gain (specimen mass gain + spalled oxide) and spalled oxide mass per unit area for various commercial alloy specimens (compositions in Table 1) at 1000 °C in laboratory air after 30, 500 h cycles (15 kh total exposure). Data from Pint<sup>12</sup> and Pint and Keiser.<sup>14</sup>

**Figure 2** Time to accelerated attack as a function of specimen thickness for NiCr alloy 230 and alloy MA956 (see Table 1 for compositions) for exposure in 100 h cycles at 1100 °C in laboratory air. For MA956, the time is for the onset of Fe-rich oxide formation and increases significantly with thickness. For NiCr, the times are to total mass gains of 20–40 mg cm<sup>-2</sup> that do not change significantly with thickness. Values of  $n$  are given for eqn [5]. Data from Pint<sup>12</sup> and Pint and Keiser.<sup>14</sup>

However, the lifetime predictions made by NASA using modeling methods like Cyclic oxidation simulation program (COSP)<sup>17</sup> for  $\beta$ -NiAl and NiAl + Zr, usually with criteria of 250  $\mu$ m metal consumption in <10 kh and 1 h thermal cycles, showed maximum

temperatures of  $\sim 1250$  °C for NiAl + Zr<sup>18</sup> which contains a substantially higher initial Al content ( $\sim 50$  at.%) than most alumina-forming alloys. Even with a longer cycle time between cooling to room temperature, the maximum temperature used to achieve respectable lifetimes will not be significantly higher. This is because scale spallation must also be considered. Specifically, the strain energy per unit volume ( $W^*$ ) is defined<sup>19</sup> as

$$W^* = E_{\text{ox}}(\Delta T \Delta \alpha)^2(1 - \nu) \quad [1]$$

(where  $E_{\text{ox}}$  is the elastic modulus of the oxide,  $\Delta T$  is the temperature drop,  $\Delta \alpha$  is the coefficient of thermal expansion (CTE) difference between metal and oxide, and  $\nu$  is Poisson's ratio) in a thick alumina scale ( $\xi > 10 \mu$ m) will exceed the work of adhesion ( $W_{\text{ad}}$ ), that is, the work needed to form unit area of oxide and metal interfaces from unit area of interface of the metal–oxide interface<sup>20</sup>:

$$W_{\text{ad}} = \gamma_{\text{ox}} + \gamma_{\text{met}} - \gamma_{\text{int}} - \xi W^* \quad [2]$$

where the  $\gamma$ 's are the surface energies of the oxide, metal and interface. This leads to spallation and the Al consumed to regrow the spalled oxide significantly increases the Al consumption rate, after spallation begins. For example, the time needed to form a 10  $\mu$ m thick alumina scale is  $\sim 200$  h at 1200 °C but  $\sim 10$  kh at 1050 °C. Thus, the prime temperature range of interest for commercial applications of alumina-forming alloys is  $\sim 1050$ –1250 °C.

Because of the high temperatures involved, applications for alumina-forming alloys are often limited by their creep strength. For ferritic alumina-formers such as FeCrAl, some of the primary applications are as heating elements (e.g., Kanthal alloys) and in foil (30–70  $\mu\text{m}$ ) form as catalyst supports in automotive applications<sup>21</sup> as well as catalytic combustion to lower emissions from turbine engines.<sup>22</sup> Some of the less discussed applications are: (1) dissipative resistor banks, which are used to eliminate excess electricity for regenerative braking of diesel electric locomotives,<sup>23</sup> (2) reinforcement for molded refractory products, and (3) thermal protection shields.

Oxide dispersion strengthened (ODS) FeCrAl alloys have been the subject of considerable research and will be discussed throughout this chapter. The use of yttria dispersions increases the creep strength of these materials but the drawback is that the powder metallurgy (PM) processing<sup>24</sup> increases their cost significantly. These alloys have been investigated for a variety of high temperature applications including heat exchangers running at  $\sim 1100^\circ\text{C}$ .<sup>25</sup> **Figure 3** gives the creep rupture life for 125  $\mu\text{m}$  thick PM2000 foil compared to 100  $\mu\text{m}$  thick Ni-based alloys. The higher creep strength of this material allows a wider range of applications to be considered. However, manufacturers (e.g., Plansee and Special

Metals) are discontinuing production because of the limited market. Less expensive dispersion strengthened alloys such as Kanthal alloys APM<sup>®</sup> and APMT<sup>®</sup> also have been developed and are more widely available. Because of their higher strength, dispersion strengthened alloys have better dimensional stability at high temperature and APMT is available in tube form. Because of its strength and oxidation resistance, APMT was selected as a heat shield material in the heat exchanger of a biomass gasifier.<sup>14</sup>

Nickel-based alumina-forming alloys generally have better high temperature strength than wrought ferritic alloys and can be considered for a broader range of applications. Alloys such as 214 have similar oxidation resistance as FeCrAl alloys and are available in foil form, as in **Figure 3**. The second-generation of single crystal (SX) and dispersion strengthened Ni-based super alloys contain  $\sim 11$ –13 Al and have fairly good oxidation resistance, even without a coating.<sup>16,27,28</sup> To further improve their oxidation resistance, Ni-based superalloys are often coated with a higher Al content NiAl or NiCoCrAl composition (dealt elsewhere in **Chapter 1.27, High Temperature Coatings: Protection and Breakdown**). When sufficient Al is added to an alloy for alumina scale formation, other properties such as strength, phase stability, and weldability may be adversely affected. Nevertheless, cast NiCrAlY alloys have been developed for steam reforming applications where the formation of a chemically inert alumina scale has an additional benefit of reducing surface coke formation.<sup>29</sup>

Cobalt-based alumina-forming alloys are also primarily used as coatings, especially for hot corrosion (see **Section 1.24.6.2**) or high temperature wear resistance applications. The addition of Co in MCrAlY coatings is known to change the phase composition and mechanical behavior.<sup>30,31</sup> Minimal research has been reported on Co-based alumina-forming alloys in the last 20 years and their application seems somewhat specialized and limited at present.

**Figure 3** Creep rupture life at 100 MPa for 100  $\mu\text{m}$  thick foil of Ni-base alloys 214 and 625 and for 125  $\mu\text{m}$  thick alloy PM2000 foil (alloy compositions in **Table 1**). Materials selection for high temperature (750–1000°C) metallic recuperators for improved efficiency microturbines, ASME Paper #2001-GT-445, Presented at the International Gas Turbine and Aeroengine Congress and Exhibition, New Orleans, LA, June 4–7, 2001.

#### 1.24.1.2 Other Applications for Thermally-Grown Alumina Layers

One of the more interesting aspects of alumina-forming alloys is the usage of the alumina layer in other applications besides for oxidation resistance. After forming a dense-adherent alumina layer at high temperature, this layer could be used at lower temperatures where further alumina formation would be limited. Some of the properties of interest are electrical (insulating),

chemical inertness (for chemical processing applications) and wear resistance. Besides microelectronics, one application where alumina is attractive for its electrical resistance is, as a coating to decrease the magneto-hydrodynamic force in magnetic confinement fusion reactors. Alumina could be used as a coating or inside a flow channel insert.<sup>32</sup> Another property of interest is hydrogen or tritium permeability.<sup>33</sup> Alumina has a hydrogen permeability several orders of magnitude lower than most metals (**Figure 4**). Because of the recent interest in the use of hydrogen as a clean-burning fuel and in the use of more traditional weapons and nuclear energy applications (e.g., hydride fuels), permeation barriers are widely desired but frequently ineffective.<sup>35</sup> Also nuclear-related, alumina can be a corrosion barrier in liquid Pb (or Pb eutectics like Pb–Li or Pb–Bi) systems<sup>36</sup> but not liquid Li, which dissolves alumina<sup>37</sup> because of the thermodynamic stability of  $\text{LiO}_2$ .<sup>38,39</sup> Even with a decreased Li activity in Pb–Li eutectic, the Li can transform a pre-formed  $\alpha\text{-Al}_2\text{O}_3$  scale on alloy PM2000 to  $\text{LiAlO}_2$  after exposure to Pb–Li at 600–800 °C.<sup>40</sup>

### 1.24.2 Selective Oxidation

The first issue to consider as far as alumina-forming alloys are concerned is the need for selective oxidation of Al in the alloy to form alumina and the minimum alloy Al content,  $C_{\min}$ , needed to form alumina in the alloy. This minimum value is not necessarily equal to the minimum concentration

**Figure 4** Hydrogen permeability as a function of reciprocal temperature for various pure metals and alumina. Data from Fowler *et al.*<sup>33</sup> and Steward.<sup>34</sup>

needed to reform Al after an alumina scale had already been established,  $C_b$ .<sup>41,42</sup> The basic concept of selective oxidation was discussed in **Chapter 1.09, Thermodynamics and Theory of External and Internal Oxidation of Alloys**. For alumina-forming alloys, the general interest is the behavior of M–Al and M–X–Al, where X is normally Cr but can also be another element, such as Mn, with nobility between M and Al, the so-called third element.<sup>43</sup>

#### 1.24.2.1 M–Al Alloys

For Ni–Al alloys, an early work by Pettit<sup>44</sup> considered the thermodynamics of the system as well as experimental evidence which indicated that kinetic issues dominate  $C_{\min}$ . The thermodynamic calculations indicated <1 ppm Al at the alloy surface was needed for NiO or  $\text{NiAl}_2\text{O}_4$  (spinel) to be stable. However, experimental work, summarized in **Figure 5** showed that much higher Al contents were needed for transition from Al internal oxidation with an external NiO scale (Region I) to an external alumina formation (Region III) in 0.1 atm  $\text{O}_2$ . (An over-lying spinel layer is formed at up to ~40 at.% in the  $\beta$ -NiAl phase field.<sup>45</sup>) The effect of temperature was to slightly lower  $C_{\min}$  at higher temperatures. Even in a CO/ $\text{CO}_2$  mixture (2:1) where NiO was not stable, the

**Figure 5** Relationship between oxidation temperature and Al content on the reaction products formed on Ni–Al alloys oxidized in 0.1 atm  $\text{O}_2$ . The various regions are: I – primarily NiO + Al internal oxidation, II – initial spinel ( $\text{NiAl}_2\text{O}_4$ ) +  $\text{Al}_2\text{O}_3$  formation, but eventual NiO, III – primarily  $\text{Al}_2\text{O}_3$ . The bold line indicates the transition between internal and external oxidation in CO– $\text{CO}_2$  mixtures where  $\text{Al}_2\text{O}_3$  was the only stable oxide. Adapted from Pettit<sup>44</sup> with the Al content changed to atomic%. The dashed line is an observation for Ni–22Al + Hf where the initial  $\text{NiAl}_2\text{O}_4$  +  $\text{Al}_2\text{O}_3$  scale was stable for 1000 h at 1000–1200 °C. Pint, B. A. Unpublished oxidation data, ORNL, Oak Ridge, TN, 1994–2008.

solid bold line in **Figure 5** shows a fairly high Al content needed for transition from internal to external alumina formation. Thus, kinetic factors such as the scale growth rate and diffusivities in the metal and oxide dominate the selective oxidation process.

Values of  $C_{\min}$  for Fe–Al alloys have been reviewed<sup>46</sup> and **Figure 6** shows a summary of  $C_{\min}$  values found during oxidation in air or  $O_2$ .<sup>47–52</sup> As discussed by Pint *et al.*,<sup>51</sup> a distinct difference between complete alumina scale formation and Fe-rich oxide formation is clear at  $\geq 1000^\circ\text{C}$  but can be more difficult to differentiate at lower temperatures, especially at  $600\text{--}700^\circ\text{C}$  where an exclusive alumina scale is difficult to form on binary Fe–Al alloys and there is no significant difference in mass gain between high and low Al contents. One reason for the large range of values in **Figure 6** may be because of the interpretation. If the criterion is that no Fe-rich oxide formed using a visual assessment of scale color, then the contents of  $\sim 18\text{--}20\%$  Al are typically needed. However, the same requirement for Ni–Al alloys in air would require  $C_{\min} > 35\%$ . A more appropriate criterion is that a continuous alumina scale forms underneath the transient, base metal oxide. This is the criteria used in **Figure 5**. **Figure 7** gives an example for  $Y_2O_3$ -dispersed Fe–20Al where large faceted Fe-rich grains were observed at the gas

interface after oxidation at  $1100^\circ\text{C}$  but underneath is a fully-developed columnar alumina scale. Subsequent sections will discuss some of the other reasons for the scatter in **Figure 6**. Recent calculations by Zhang *et al.*<sup>53</sup> using relevant Fe–Al rate constants predicted much lower  $C_{\min}$  values ( $0.5\text{--}4.5\%$  depending on the assumptions) which does not agree with the experimental results summarized in **Figure 6**.

One issue that can affect  $C_{\min}$  is time, that is, the length of exposure, and whether the alloy can maintain the alumina scale during extended exposures. Region II in **Figure 5** indicates where an initial external alumina scale was not sustained and a faster growing NiO formed. The likely explanation was Al depletion in the metal which did not allow the sustained formation of alumina.<sup>44</sup> This point might be more relevant to the discussion of lifetime, i.e., the amount of time an alloy can sustain the formation of an alumina scale (discussed in **Sections 1.24.4.4 and 1.24.5**). Nevertheless, the usefulness of  $C_{\min}$  plots may be questionable if the specified level of Al cannot sustain alumina formation. For example, Hf-doped Fe–11Al at  $1200^\circ\text{C}$  (**Figure 6**) only survived for 300 h before breakaway oxidation.<sup>52</sup> Thus, these plots provide a defined minimum Al level and not a target Al content for alloy development.

**Figure 6** Summary of critical Al contents for Fe–Al alloys from various studies. The values for powder metallurgy (PM) alloys<sup>51</sup> were decreased by  $\sim 2\%$  because this Al was tied up as oxides in these materials. Generally, these values were determined for exposures of  $\sim 100$  h. Data from Sykes and Bampfylde,<sup>47</sup> Saegusa and Lee,<sup>48</sup> Devan and Tortorelli,<sup>50</sup> Pint *et al.*,<sup>51</sup> and Pint and Wright.<sup>52</sup>

### 1.24.2.2 MCrAl and M–X–Al Alloys

Most commercial alumina-forming alloys are based on MCrAl rather than M–Al compositions. The main

**Figure 7** SEM secondary electron image of scale fracture cross section after 100 h at  $1100^\circ\text{C}$  in air on Fe–20Al– $Y_2O_3$ . An outer Fe-rich oxide formed over the inner  $\alpha\text{-Al}_2O_3$  layer because of the relatively low Al content in this alloy. Adapted from Pint, B. A.; Leibowitz, J.; DeVan, J. H. *Oxid. Met.* **1999**, *51*, 181–197.

reason is that the addition of Cr (typically 10–25%, see Table 2) allows alloys with much lower Al contents to form a continuous alumina-scale than observed in M–Al compositions. Since Al tends to have detrimental effects on mechanical and fabrication (i.e., rolling, joining) properties, minimizing the Al content is often a goal in alloy development. The effect of Cr is described as a third element effect.<sup>43,53–55</sup> There is still a disagreement as to whether the third element (1) acts as an oxygen ‘getter,’ (2) changes the Al activity, (3) increases the Al diffusivity, (4) increases the volume of internal oxides in the alloy, (5) simply decreases the concentration of base metal in the alloy, and/or (6) acts by some other mechanism. Most agree that the third element effect is more complex than the early explanation of Wagner.<sup>54</sup>

To illustrate the performance of Ni–Cr–Al alloys (Figure 8) shows examples of Ni–(17–30)Cr alloys with various Al additions oxidized in 100-h cycles at 1200 °C. Lower Al additions, 2.5–4.8% such as in alloys 617 and 602CA resulted in high mass gains similar to alloy 230 without Al. Alloy 602CA does not form an external alumina layer at 1200 °C; only internal Al oxidation is observed.<sup>56</sup> However, the ~6% Al addition in alloys 702 and 693 resulted in a significantly lower mass gain after the initial transient formation of Ni- and Cr-rich oxides. Further increases in Al content, for example, alloy 214, decreased the transient (i.e., Ni-rich) oxide formation

**Figure 8** Total mass gain (specimen + spalled oxide) during 100 h cycles at 1200 °C in laboratory air for various Ni–Cr and Ni–Cr–Al alloys (see Table 1). Generally, the mass gain decreases with Al content due to the formation of a protective alumina scale with NiAl + Hf having one of the slowest growth rates of any alumina-former. Data from Pint.<sup>12</sup>

and mass gain but did not decrease the long-term growth rate. With the presence of Cr in these alloys, the Al level needed for alumina formation, ~6%, is significantly lower than the Al levels discussed in binary Ni–Al alloys (Figure 5).

Composition effects can be summarized in so-called oxide maps.<sup>57–59</sup> Figure 9 shows a Ni–Cr–Al oxide map with some of the data points from Figure 8. The three oxide regions, very similar in composition to the work of Giggins and Pettit<sup>57</sup> (and not at all like Wallwork and Hed<sup>58</sup>) are: I – Ni-rich scale with Al internal oxidation, II – Cr-rich scale with Al internal oxidation (e.g., alloys 602 and 617), and III – continuous Al<sub>2</sub>O<sub>3</sub> scale. Obviously, the most oxidation-resistant alumina-forming alloys will be in region III.

A similar map was constructed for CoCrAl.<sup>57</sup> The main difference between CoCrAl and NiCrAl was that much higher Cr and Al contents were needed to achieve alumina scale formation, on the order of 20% Cr and 20% Al. The need for higher Cr and Al contents in Co-based alloys was also observed in a separate study.<sup>60</sup> Alloys based on TiCrAl are covered in a separate chapter.

Similarly to NiCrAl, in Fe-based alloys, as little as 13Cr is added to Ohmalloy<sup>®</sup> alloys combined with 5.2%Al to form alumina, Table 2.<sup>23</sup> In both Fe- and Ni-based alloys, a reasonable starting point for a standard alumina-forming MCrAl composition

**Figure 9** Schematic of the oxide map for Ni–Cr–Al and the location of the commercial alloys from Figure 8. Region I is for alloys which form Ni-rich oxide and Al internal oxide, Region II alloys form a Cr-rich oxide and Al internal oxide, and Region III alloys are able to form a continuous alumina scale. Map based on Giggins and Pettit,<sup>57</sup> alloy data from Pint.<sup>12</sup>

is ~20% Cr and ~10% Al (~5 wt%). Obviously, lower Cr and Al contents can form alumina, as demonstrated by both commercial and laboratory alloys (Tables 1 and 2). Higher Cr contents (>25%) lead to a decrease in workability and ductility and in FeCrAlY to a decrease in the incipient melting temperature of any Y-rich precipitate.<sup>61</sup>

While Cr is the most popular third element addition, other elements are used or have been investigated. To replace Cr, Mn additions have been investigated in Fe-based alloys by several authors.<sup>62,63</sup> These austenitic alloys have good wear properties but their oxidation resistance, particularly above 900 °C, is compromised of the formation of Mn-rich oxides. The addition of Si has been investigated in Fe–Al alloys<sup>64</sup> and has been shown to exhibit a third element effect in Ni–Si–Al alloys.<sup>65</sup> (Large Si additions are mainly an academic exercise as Si has detrimental effects on ductility and fabricability.) In Fe–Al–Si alloys, higher Si contents led to a decrease in oxidation rate. Also, Ni additions to Fe–Al alloys have been attempted.<sup>66</sup> However, the addition of Ni did not appear to improve the oxidation behavior at 600–800 °C compared to binary Fe–Al.

Quaternary additions on selective oxidation have been explored. In the case of alumina-forming austenitics (AFA, see example in Table 2), where low levels by Al are needed to retain a fully austenitic matrix (and retain creep-resistance<sup>67,68</sup>), additions of Nb have been found to influence whether the alloy forms an alumina scale at 800 °C (Figure 10).<sup>69</sup> At constant 5 or

6 at.% Al in Fe–15Cr–19Ni, increasing the Nb content decreased the mass gain after 500 h at 800 °C. At low levels of Nb, mass losses were observed due to the formation of a thick Fe- and Cr-rich oxide. The effect of Y on selective oxidation also has been investigated. Castello and coworkers<sup>70</sup> reported improved selective oxidation in Ni–12.9Al–11.9Cr–7.5C–0.11Y compared to the Ni–Al + Cr<sub>3</sub>C<sub>2</sub> alloy without Y. They attributed the effect to Y reducing the growth rate of the initially-formed Cr-rich scale. Figure 6 shows that Hf-additions to Fe–Al alloys decreased the critical Al content needed to form alumina.<sup>52</sup> Studies of Y<sub>2</sub>O<sub>3</sub> additions in PM Fe–Al alloys did not find a benefit of Y on selective oxidation compared to PM alloys with an Al<sub>2</sub>O<sub>3</sub> dispersion.<sup>51</sup> Rather, the fine-grain size of the PM Fe–Al alloys was thought to influence selective oxidation.

### 1.24.2.3 Alloy Grain Size Effect

Alloy grain size effects on selective oxidation are not widely appreciated in high temperature oxidation but are extremely important and often ignored as specimen alloy grain size is not always specified in literature papers. Early work on chromia-forming stainless steels showed that a fine-grained substrate was more oxidation resistant.<sup>71–73</sup> More grain boundaries increased the flux of Cr to the surface along these fast diffusion paths. This concept was used in alumina-forming alloys by Maloney and Yurek<sup>74,75</sup> where rapid solidification was used to achieve a fine grain size in Fe–2.8Cr–4.7Al alloys and TiB<sub>2</sub> dispersions were used to stabilize the fine grains. As discussed in the previous section, these low levels of Cr and Al are well below commercial FeCrAl alloys, Table 2. Figure 11 shows the low mass gain at 600 °C and 700 °C for the fine-grained material compared to the conventionally-cast, coarse-grained Fe–2.8Cr–4.7Al specimens. While the TiB<sub>2</sub> additions may have contributed to the effect, Figure 12 shows a thicker oxide formed over a large grain in the TiB<sub>2</sub>-dispersed FeCrAl specimen. A thin Al-rich oxide (arrow) formed over the small grains in the substrate.

Goedjen and Shores<sup>76</sup> investigated the effect of grain size on NiCrAlY alloys. They found a decreased transient mass gain (i.e., less Ni-rich oxide formation) with finer grains but no change in the steady-state alumina scale growth rate. More recently, coating processes that produce fine-grained NiCrAl coatings have been found to have better selective oxidation.<sup>77,78</sup> Collectively, these results suggest that for low Al content alloys, reducing the grain size will improve

**Figure 10** Specimen mass gain for Fe–15 at.% Cr–19Ni alloys with various Al and carbide forming elements (Nb, Ti, V) after 500 h (5, 100-h cycles) in laboratory air at 800 °C. Data from Brady *et al.*<sup>69</sup>

**Figure 11** Mass change for conventional processed and fine-grained Fe-2.5 wt% Cr-2.5Al (2.8 at.% Cr-4.7Al) alloys made by several spray and powder processes. By using  $\text{TiB}_2$  to keep a fine grain size, an Al-rich oxide was formed at 600–700 °C, thereby decreasing the mass gain of these alloys compared to conventional, coarse-grained material with the same Cr and Al content. Maloney, M. J. Ph.D. Thesis, Massachusetts Institute of Technology, Cambridge, MA, 1989, Maloney, M. J.; Yurek, G. J. In *Composites/Corrosion-Coatings of Advanced Materials*, Proceedings IMAM-4; Kimura, S., Kobayashi, A., Umekawa, S., Nii, K., Saito, Y., Yoshimura, M. Eds.; Materials Research Society: Pittsburgh, PA, 1989; Vol. 1, pp 383–388.

**Figure 12** SEM secondary electron image of a polished cross-section of Fe-2.8 at.% Cr-4.7Al-1.5Ti-2.3B after 50 h at 700 °C. Ph.D. Thesis, Massachusetts Institute of Technology, Cambridge, MA, 1989.

the possibility of forming an alumina scale. Furthermore, this effect will probably be most critical at lower temperatures 600–1000 °C where selective alumina formation is more difficult because of slow diffusion rates and less critical at higher temperature >1100 °C where diffusion in the alloy is much faster.

#### 1.24.2.4 Precious or Platinum Group Metal (PGM) Effect

One of the more intriguing results of this decade in alumina-forming alloys is the work on  $\gamma$ - $\gamma'$  Ni-Pt-Al compositions.<sup>79–81</sup> The addition of a PGM such as Pt (or Ir, Pd, Rh, etc.)<sup>81–83</sup> to a base Ni-(16–22)Al alloy improves selective oxidation (i.e., decreases the formation of Ni-rich oxide) such that the alloy becomes a primary alumina former, similar to  $\beta$ -NiAl. However, TEM (or careful metallography) has found that a thin Ni-rich oxide layer does form on these alloys even with 30% Pt.<sup>82,83</sup> Improved selective oxidation had been previously observed in NiCrAl + Pt alloys by Felten,<sup>84</sup> Pt-containing superalloys by Tatlock and Hurd<sup>85</sup> and with Pt on the surface of MCrAl alloys.<sup>86</sup>

To illustrate the PGM effect on transient oxidation, **Figure 13** shows the mass gain after a 500 h isothermal exposure at 1000 °C as a function of PGM addition in cast Ni-22Al±Hf alloys.<sup>82,83</sup> The mass gain for Ni-48Al + Hf serves as a baseline for alumina formation with no Ni-rich oxide formation. The alloys without a PGM addition show a higher mass gain due to the formation of a Ni-rich scale with some contribution due to Hf internal oxidation.

**Figure 13** Total mass gain (specimen + spalled oxide) after a 500 h isothermal exposure at 1000 °C in laboratory air for various precious metal (PM) and Hf additions to Ni-22Al alloys. Data from Pint *et al.*<sup>82,83</sup>

With increasing PGM content, the mass gain decreased. An Ir addition showed a similar benefit as Pt at the 5% level but 10–20% Pd, which is significantly less expensive than Pt, was not as effective due to formation of additional phases.<sup>83</sup> As an example of the alumina scale formed on these alloys, **Figure 14** shows scale cross-sections after 2000, 1-h cycles at 1100 °C. Without a Hf addition, the alumina scale on Ni-22Al-10Pt is similar in thickness to that formed on  $\beta$ -Ni-50Al-5Pt (**Figures 14(a) and 14(b)**). The addition of 0.4 Hf to Ni-22Al-10Pt decreased the oxide thickness but some internal oxidation of Hf was evident (**Figure 14(c)**).

The  $\gamma$ - $\gamma'$  Ni-Pt-Al compositions are primarily considered for coatings on NiCrAl-based superalloys but some effort has been dedicated to alloy development.<sup>87</sup> By suppressing the formation of Ni-rich oxides with the associated weak  $\text{Al}_2\text{O}_3$ - $\text{NiAl}_2\text{O}_4$  interface,<sup>88,89</sup> these compositions can be used as bond coatings in thermal barrier coatings (TBCs). Such  $\gamma$ - $\gamma'$  coatings are attractive because (1) they can be formed simply by interdiffusing a plated Pt layer into the surface of the super alloy (i.e., a Pt diffusion coating rather than a Pt-modified  $\beta$ -phase aluminide), (2) Al interdiffusion is less of an issue because the phase composition of the coatings is the same as the super alloy substrate<sup>79</sup> and Pt appears to decrease the Al activity in the coating,<sup>90</sup> thereby creating a chemical potential gradient for Al to diffuse from the substrate into the coating (rather than

**Figure 14** Light microscopy of polished cross-sections after 2000, 1 h cycles at 1100 °C in O<sub>2</sub> (a) Ni-22Al-10Pt, (b) Ni-50Al-5Pt, and (c) Ni-22Al-10Pt + 0.4Hf. Adapted from Pint, B. A.; More, K. L.; Wright, I. G. *Oxid. Met.* in preparation.

out of an Al-rich coating), and (3) their high strength compared to  $\beta$ -NiAl and MCrAlY coatings<sup>82</sup> is thought to increase their resistance to thermal mechanical fatigue. When the  $\gamma$ - $\gamma'$  coating contains 5–10% Cr, either by interdiffusion from the substrate or by addition as a part of a secondary coating process, the hot corrosion resistance is improved.<sup>91</sup> One concern about these coatings is the depletion of Pt due to interdiffusion with the super alloy, which is significant at 1100 °C.<sup>92</sup>

## 1.24.3 Transient Oxidation

### 1.24.3.1 Base Metal Oxide Formation

As already discussed in the previous section on selective oxidation, during the initial or transient stage of oxidation, alumina-forming alloys will tend to form some base-metal oxide (e.g., NiO, FeO<sub>x</sub>, or M-Al-O spinel, etc.), see **Figure 7**. This is illustrated in **Figure 15** for Fe-Al alloys oxidized at 900 °C. The decreasing mass gain with increasing Al content is due to a decrease in the initial transient Fe-rich oxide formation.<sup>93</sup> Because of the subsequent slow alumina scale growth, the mass gain after 5 kh is dominated by the mass gain after the first 500 h exposure (triangles in **Figure 15**). In addition to the alloy composition, the transient oxide thickness and phase composition are affected by many factors associated with the

**Figure 15** Total mass gain (specimen + spalled oxide) after 1 or 10, 500-h cycles at 900 °C in air for Fe(Al) alloys as a function of Al content. The doped alloys contained Ti, Hf, Zr, or Y and the Fe–20Cr–10Al specimen contained no dopant. For doped Fe–Al alloys (dashed line fit), the majority of the mass gain occurred during the first 500 h (triangle) when Fe-rich oxide formed. The higher mass gains for the undoped Fe–Al alloys (open squares) were due to an internal oxidation/nitridation with nearly linear kinetics. This internal oxidation was not observed for FeCrAl. Data from Pint<sup>12</sup> and Pint *et al.*<sup>93</sup>

thermodynamics and kinetics of oxide formation. Examples of thermodynamic factors are temperature and the partial pressure of the oxygen (e.g.,  $\text{H}_2$ – $\text{H}_2\text{O}$  or  $\text{CO}$ – $\text{CO}_2$  gas mixtures). Some of the kinetic factors are heating rate, alloy grain size (affecting the flux of Al in the alloy) and surface preparation which can affect the number of fast-diffusion paths in the near surface region (e.g., grinding versus acid etching).

Oxidation temperature is a critical factor for transient oxide because of the slow-formation of alumina below 800 °C. (A slow heating rate to a higher temperature can have a similar effect.) Alumina may be the thermodynamically stable phase but kinetics often dominate, allowing rapid base-metal oxidation. A simple strategy to enhance alumina formation is to preoxidize at a higher temperature where an alumina scale forms more readily. Figure 16 gives an example of this strategy for alloy 214 foil ( $\sim 50 \mu\text{m}$  thick) preoxidized for 2 h at 1100 °C. Because of the difficulty in forming alumina at low temperatures, the parabolic rate constant after 5000 h was higher at 700 °C ( $8 \times 10^{-16} \text{ g}^2 \text{ cm}^{-4} \text{ s}^{-1}$ ) than at 800 °C ( $2 \times 10^{-16} \text{ g}^2 \times 10^{-16} \text{ g}^2 \text{ cm}^{-4} \text{ s}^{-1}$ ) (Figure 16(a)). The observed

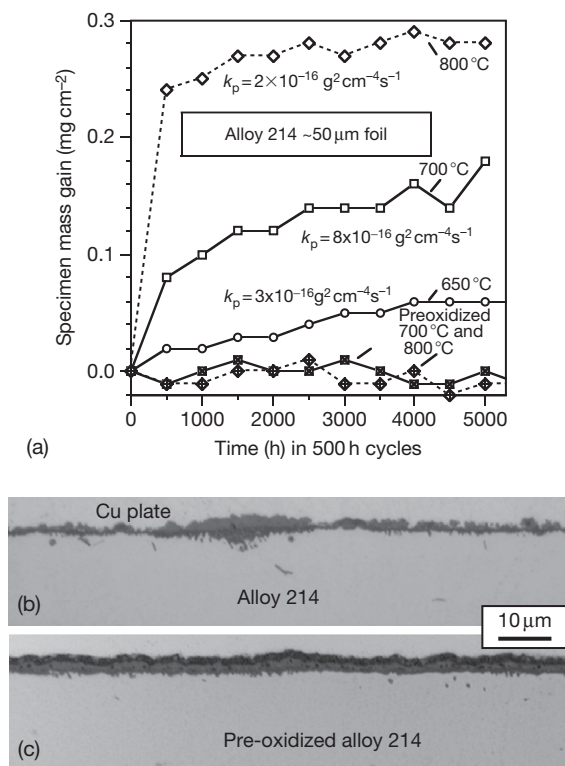

mass gains reflect the formation of a Ni- and Cr-rich transient oxide which is nonuniform (e.g., Figure 16(b)). (Even at 1100 °C, a thin (0.5–1  $\mu\text{m}$ ) external layer of  $\text{Ni}(\text{Al,Cr})_2\text{O}_4$  formed on this alloy with only 8.7 at.% Al (see Table 2). But this exposure was sufficient to develop a continuous, underlying  $\alpha$ - $\text{Al}_2\text{O}_3$  layer.<sup>94</sup>) With the preoxidation ( $< 0.2 \text{ mg cm}^{-2}$  mass gain), no further mass gain was measured during 10 kh exposures in air at 700 or 800 °C.<sup>12</sup>

The differences in oxidation behavior among Co-, Ni-, and Fe-based alumina-forming alloys were studied at 1000 and 1200 °C by Stott *et al.*<sup>60</sup> The critical factors identified were  $D_{\text{Al}}$  and O permeability in the alloy. With similar Cr and Al contents, Co-based alloys formed thicker transient oxides that were attributed to the fast growth rate of CoO and the relatively slow Al diffusivity in Co-based alloys. (Stated differently, higher Cr and Al contents were needed in Co-based alloys to quickly form alumina.) The growth rate of FeO is faster, which is important at breakaway (see Section 1.24.5), but faster Al diffusivity in ferritic FeCrAl alloys resulted in rapid alumina formation. A less comprehensive study of Fe, Ni, and Co–Al alloys by Hagel found similar results.<sup>95</sup>

The work of Kear *et al.*<sup>96</sup> was one of the earliest microstructure studies of the transient stage oxidation of NiCrAl. By reducing the oxygen partial pressure, NiO and Ni-rich spinel-type oxide formation was suppressed at 1000 °C resulting in a mixture of  $\text{Cr}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$ . A subsequent characterization was reported by Smialek and Gibala.<sup>97</sup> On FeCrAl, there is typically very little transient base-metal oxidation. Quadakkers and coworkers<sup>98</sup> used the Fe and Cr in the outer scale to mark the original metal interface and study the alumina growth mechanism. Figure 17 gives an example of the type of transient scale on ODS FeCrAl after 2 h at 1000 °C in  $\text{O}_2$ .<sup>40</sup> The Fe and Cr maps (Figures 17(b) and 17(c)) show that Cr and Fe were concentrated in a thin ( $\sim 100 \text{ nm}$ ) outer layer after these conditions.

### 1.24.3.2 Cubic Alumina Phases

One of the most critical transient oxidation issues for alumina-forming alloys is the formation of metastable cubic  $\text{Al}_2\text{O}_3$  phases (e.g.,  $\gamma$ ,  $\delta$ ,  $\theta$  phases). Their formation can be considered as a transient phenomenon because, given time and temperature, these metastable phases generally transform to the stable  $\alpha$  phase. However, because these cubic phases are more defective than  $\alpha$ , they allow faster diffusion and grow at a faster rate.<sup>95,99,100</sup>

**Figure 16** (a) Specimen mass gains for alloy 214 (NiCrAl, see Table 2) foil (~50 μm) with and without preoxidation exposed for 500 h cycles in laboratory air at 650 °C, 700 °C, and 800 °C. Polished cross-sections for the specimens shown in (a) after exposure in laboratory air at 800 °C, (b) as-received foil specimen oxidized for 5000 h, and (c) preoxidized (2 h at 1100 °C in dry O<sub>2</sub>) foil after 10000 h. Data from Pint.<sup>12</sup>

The formation of cubic alumina phases on alumina-forming alloys was discussed in the early literature.<sup>95</sup> However, the possibility of forming these metastable phases, rather than α, was not discussed for many years and probably led to the controversy regarding the growth mechanism of alumina scales in the 1980s. The observation of growth by outward Al transport was assumed to be for an α-Al<sub>2</sub>O<sub>3</sub> scale but, based on the oxidation time and temperature, was likely θ-Al<sub>2</sub>O<sub>3</sub>.<sup>101</sup> This issue will be further discussed in Section 1.24.4.2.

The hallmark of cubic alumina phases is the gas-side blade or whisker morphology often observed. Much of the cubic alumina scale characterization work has been done on β-NiAl,<sup>102–105</sup> because of the cubic epitaxy with the β phase and because Fe and Cr in the substrate tend to help nucleate α phase.<sup>100,106</sup> However, at lower temperatures (<950 °C), cubic alumina scales form even on FeCrAl. Typical surface

**Figure 17** Cross-section of the α-Al<sub>2</sub>O<sub>3</sub> scale formed on PM2000 (ODS FeCrAl, see Table 1) after 2 h at 1000 °C in dry O<sub>2</sub> (a), STEM high angle annular dark field image and EDS X-ray maps from the box in (a): (b) Fe, (c) Cr, (d) Y, and (e) Ti. Adapted from Pint, B. A.; More, K. L. *J. Nucl. Mater.* 2008, 376, 108–113.

morphologies on commercial FeCrAl foil are shown in Figure 18. The outward growing features are minor at 700 °C but are very evident at 800 °C (Figure 18(b)). After long-term exposure at 900 °C, there is little evidence of outward transport and the scale has completely transformed to α-Al<sub>2</sub>O<sub>3</sub> (Figure 18(c)). However, aluminized foils (aluminized to increase the Al reservoir) showed more distinct remnants of outward growth (Figure 18(d)). This is consistent with work on NiAl where surface enrichment of Al by ion implantation led to more cubic alumina formation.<sup>107</sup> Cubic alumina phases

**Figure 18** SEM secondary electron plan view images of the alumina scale morphology formed on  $\sim 50 \mu\text{m}$  commercial FeCrAl foils after exposure in laboratory air: (a) FeCrAl + Y,Hf, 700°C 10 kh, (b) FeCrAl + Y,Hf, 800°C, 10 kh, (c) FeCrAl + Mm (mischmetal), 900°C, 50 kh, and (d) aluminized FeCrAl + Mm, 900°C, 50 kh. Adapted from Pint, B. A. Unpublished oxidation data, ORNL, Oak Ridge, TN, 1994–2008.

such as  $\theta$  also have been observed on bulk FeCrAl alloys at 900°C.<sup>104,108,109</sup> For Ni-based alloys, cubic aluminas are less common because they tend to form Ni-rich oxides first and the nucleation of alumina beneath this layer apparently favors  $\alpha\text{-Al}_2\text{O}_3$  formation. The alloy 214 (NiCrAl) foils in Figure 16 do not show the high parabolic rate constants observed on FeCrAl foils (Figure 19).

The study of the alumina phase may seem an academic exercise except that there is a strong effect on performance of commercial MCrAl foils in the 700–950°C temperature range. Figure 19 shows the kinetics for commercial aluminized FeCrAl foil oxidation in air at 700–900°C. At 900°C, the initial jump in mass gain is due to the initial formation of the cubic phase. Based on the mass gain, more Al was consumed during the first 500 h exposure than during the next 10 kh of exposure, after the cubic phase had transformed to a slower growing  $\alpha\text{-Al}_2\text{O}_3$  scale. Because of the faster growth of cubic-aluminas, the parabolic rate constant at 700°C ( $1 \times 10^{-15} \text{ g}^2 \text{ cm}^{-4} \text{ s}^{-1}$ ) is comparable to the rate at 900°C (Figure 19). At 800°C, where the blade structure was most evident (Figure 18(b)), the mass gain after 10 kh is higher than at 900°C, although the rate decreased significantly during the last 2.5 kh. All of these mass

**Figure 19** Specimen mass gains for aluminized FeCrAl + Mm foil ( $\sim 50 \mu\text{m}$ ) exposed for 500 h cycles in laboratory air at 700, 800, and 900°C. The higher rate for cubic alumina phases is seen at 700°C and initially at 800°C. Data from Pint<sup>12</sup> and Dryepondt *et al.*<sup>110</sup>

gains are relatively low. However, with the foil there is a limited Al reservoir. Figure 20 shows the starting and final Al contents in these foils.<sup>110</sup> The starting Al profile in the aluminized FeCrAl is not flat because of the aluminization step. As expected, the Al content drops with exposure time at 900°C with very little Al remaining after 50 kh. However, because of the faster growth of the cubic alumina scale, the foil was almost completely depleted of Al after only 10 kh at 800°C (Figure 20) is similar to other observations for FeCrAl foils in this temperature range.<sup>111</sup>

Because of the use of these foils in automotive catalytic converters and other applications operating in this temperature range, there is considerable concern about the increasing Al depletion due to transient oxide formation. Various treatments have been developed to speed the transformation to an  $\alpha\text{-Al}_2\text{O}_3$  scale.<sup>112</sup> Small ion dopants such as Ti are known to speed the transformation from  $\theta$  to  $\alpha\text{-Al}_2\text{O}_3$ ,<sup>113,114</sup> Therefore, a  $\text{TiO}_2$  slurry was an effective surface modification.<sup>112</sup> Studies have shown a faster transformation to  $\alpha\text{-Al}_2\text{O}_3$  in the presence of  $\text{H}_2\text{O}$ ,<sup>112,115</sup> although an earlier study found the opposite effect.<sup>116</sup> Thus, a higher temperature pretreatment in  $\text{H}_2\text{-H}_2\text{O}$  is another strategy to quickly form an  $\alpha\text{-Al}_2\text{O}_3$  scale.

Once a continuous  $\alpha\text{-Al}_2\text{O}_3$  scale has formed, the transient stage of oxidation is completed and the steady-state period of oxidation begins.

**Figure 20** Electron probe microanalysis using wavelength dispersive spectroscopy Al profiles of the aluminized FeCrAl + RE foil after various exposures in laboratory air. The higher depletion after 10 kh at 800 °C compared to 10 kh at 900 °C is consistent with the mass gain data in [Figure 19](#) and is attributed to the formation of a faster-growing metastable cubic alumina scale. Data from Pint<sup>12</sup> and Dryepondt *et al.*<sup>110</sup>

#### 1.24.4 Steady-State Oxidation

At the completion of the transient stage of oxidation, a complete alumina scale would have formed and subsequent oxidation should be controlled by the properties of this layer. This section will consider the performance of this layer and the factors that affect it. This will be a general discussion with examples given for various materials. The issues relevant to steady-state alumina formation have been reviewed several times.<sup>9,46,117</sup> Nominally, if the scale remains dense and adherent, steady-state oxidation should continue until the substrate is depleted in Al. This depletion will occur more rapidly if scale spallation occurs, requiring reformation of the oxide. Thus, adhesion of the oxide is also an important issue. Most commercial alumina-forming alloys contain a RE addition, for example, Y, Hf, Zr, La, Ce, etc. which strongly affects the steady state oxidation behavior. The role of RE additions will be discussed throughout. These dopants can be added as alloy additions, oxide dispersions or less effectively, as surface treatments or coatings such as slurries or ion

implantation.<sup>6,118</sup> The amount of addition can vary from the ppm level to 0.5% and one of the significant issues is optimizing the RE benefit to achieve the longest alloy lifetime.

##### 1.24.4.1 Scale Growth Rate

The previous section on transient cubic alumina formation began the discussion about growth rates. Starting with the derivation of Wagner,<sup>119</sup> the steady-state rate limiting step should be solid state diffusion through the alumina scale. Therefore, as the diffusion distance increases with time due to the formation of new oxide, the reaction kinetics are expected to be parabolic. Typically, parabolic rate constants have units in a form such as  $\text{g}^2 \text{cm}^{-4} \text{s}^{-1}$  for changes in mass data. The rate also could be expressed in terms of oxide thickness change or metal loss but mass change is the easiest parameter to quantify. For alumina in the temperature range of most interest (1050–1250 °C), the diffusion is along short-circuiting paths, likely the scale grain boundaries. As the oxide grain size increases with oxidation time, it has been argued that the kinetics are actually cubic.<sup>120,121</sup> The steady-state compressive growth stresses in an alumina scale<sup>122–124</sup> also could cause a change in the kinetics as Evans and coworkers argued for  $\text{ZrO}_2$ .<sup>125</sup> However, as will be shown for lifetime predictions of bulk alloys in the next section, the onset of scale spallation results in Al consumption kinetics which is nearly linear with time. Nevertheless, parabolic rate constants are a standard and conventional way to quantify and compare scale growth rates.

As a diffusion-controlled process, rate constants are expected to follow an Arrhenius-type relationship with temperature. [Figure 21](#) shows an Arrhenius plot of rate constants, mostly for RE-doped FeCrAl. As mentioned in the previous section, the rates are higher for cubic alumina scales such as  $\theta\text{-Al}_2\text{O}_3$ . Since cubic alumina is metastable, these scales are only present at lower temperatures, <1000 °C. At higher temperatures, only  $\alpha\text{-Al}_2\text{O}_3$  scales are formed. [Table 3](#) gives some values for FeCrAl with and without RE dopants and the associated activation energies over the range 1000–1300 °C. The activation energies for undoped  $\alpha\text{-Al}_2\text{O}_3$  are lower than that for RE-doped  $\alpha\text{-Al}_2\text{O}_3$ . The activation energy for  $\theta\text{-Al}_2\text{O}_3$  is also similar to undoped  $\alpha\text{-Al}_2\text{O}_3$ , 235  $\text{kJ mol}^{-1}$  for FeCrAl foils which is comparable to the  $\sim 200 \text{ kJ mol}^{-1}$  found for the cubic alumina scales formed on  $\beta\text{-NiAl}$ .<sup>99</sup>

**Table 3** Parabolic rate constants ( $\text{g}^2 \text{cm}^{-4} \text{s}^{-1}$ ) and activation energy ( $\text{kJ mol}^{-1}$ ) for several FeCrAl alloys. Data from Pint.<sup>129</sup>

Temperature	Undoped FeCrAl	0.08Y	0.038Hf + Y	0.020 Hf + Y
1000 °C	$3.1 \times 10^{-13}$	$(1.1\text{--}2.0) \times 10^{-13}$	$4.8 \times 10^{-14}$	$2.5 \times 10^{-14}$
1100 °C	$3.2 \times 10^{-12}$	$(4.2\text{--}4.4) \times 10^{-13}$	$1.4\text{--}3.7 \times 10^{-13}$	$0.98\text{--}1.5 \times 10^{-13}$
1200 °C	$1.4 \times 10^{-11}$	$7.5 \times 10^{-12}$	$5.6 \times 10^{-12}$	$3.5 \times 10^{-12}$
1300 °C	$(2.4\text{--}3.3) \times 10^{-11}$	$(3.6\text{--}4.4) \times 10^{-11}$	$2.2\text{--}2.3 \times 10^{-11}$	$1.1 \times 10^{-11}$
Activation energy ( $\text{kJ mol}^{-1}$ )	244	352	367	366

As can be seen in **Table 3**, RE additions can decrease the scale growth rate. However, this RE effect was not widely accepted until the past decade, particularly when it was discovered by Doychak<sup>126</sup> that Hf-doping in aluminides decreased the parabolic rate constant by a factor of 10.<sup>127–129</sup> One of the complicating factors is the additional mass gain in RE-doped alloys due to the internal oxidation of the RE addition. **Figure 22** illustrates this issue comparing the mass gains for FeCrAl and FeCrAl–0.08Y at 1100 °C. Little difference was observed after a 200 h exposure. However, for  $\text{Y}_2\text{O}_3$ -dispersed FeCrAl (PM2000) a slower rate was measured. For PM2000, there was no mass gain associated with the oxidation of Y because the Y was added to the alloy as an oxide. By minimizing the RE addition to limit internal RE oxidation, the rate constant was further decreased (**Figure 22**). **Figure 23** illustrates the effect on the oxide thickness after 1000 h at 1200 °C by minimizing the RE addition.<sup>94,129</sup> In these backscattered SEM images, the bright phases in the  $\alpha\text{-Al}_2\text{O}_3$  scale are RE-rich oxides which are defects in the scale allowing fast O transport.<sup>130</sup> Minimizing the RE addition, minimizes the number of these particles as well as RE-rich oxide penetrations that penetrate deeper into the substrate, typically referred to as pegs. Note that the lowest RE addition resulted in the thinnest alumina scale on FeCrAl (**Figure 23**).

Several RE optimization studies<sup>131–133</sup> have been conducted to determine the minimum alumina growth rate possible, as in **Figure 24**. With very low RE additions, little benefit was observed. With very high additions, the internal oxidation and entrapped RE-oxides increase the rate. However, the optimal RE levels found in laboratory scale heats may not be viable in commercial alloys with standard impurity levels of interstitials such as S, C, and N.<sup>10</sup> For ODS alloys, the level of  $\text{Y}_2\text{O}_3$  may be selected to optimize creep strength rather than a lower level that may minimize the oxidation rate.<sup>109,134</sup> The type of dopant can affect the oxidation rate. A clear effect of dopant ion size was found for chromia-forming alloys where larger ions decreased the rate more effectively

**Figure 21** Summary of parabolic growth rates reported in the literature for RE-doped FeCrAl and calculated activation energies. Rates can be split into those for  $\alpha\text{-Al}_2\text{O}_3$  and  $\theta\text{-Al}_2\text{O}_3$ . For comparison, the  $\theta\text{-Al}_2\text{O}_3$  rate data for NiAl is included.<sup>99</sup> The highlighted rates (diamonds) represent the lowest reported rates at 1100 °C and 1200 °C for Hf-doped NiAl. Other data points from Pint<sup>12</sup> and Pint.<sup>129</sup>

than smaller ions (**Figure 25**).<sup>11</sup> A similar relationship has not been established for alumina-forming alloys,<sup>135</sup> where ion size does not predict the strong beneficial effect of Hf. However, larger ions with high oxygen affinity, for example, Y, Zr, Hf, La, Ce, are all beneficial in reducing the scale growth rate. Smaller dopant ions such as Ti, Nb and Ta do not strongly affect the scale growth rate.<sup>135</sup>

As mentioned earlier, the parabolic rate constant is related to the rate of solid state ionic diffusion through the scale. However, there is no simple relationship and a number of authors have had difficulty relating the published  $\alpha\text{-Al}_2\text{O}_3$  diffusion data to alumina scale growth rates.<sup>136</sup> Using the derivation of

**Figure 22** Specimen mass gain for various FeCrAl alloys (Table 2) during isothermal oxidation at 1100 °C in dry flowing O<sub>2</sub>. The addition of Y did not decrease the reaction rate compared to undoped FeCrAl due to the additional mass gain associated with the internal oxidation of Y. When the addition is made as Y<sub>2</sub>O<sub>3</sub> or lower alloy additions, lower oxidation rates were measured. Data from Pint.<sup>12</sup>

**Figure 23** SEM backscattered electron images of the polished cross-section of the scale formed after 10, 100 h cycles at 1200 °C on FeCrAl with additions of (a) 0.08% Y and (b) 0.020% Hf/Y. Adapted from Pint, B. A.; More, K. L.; Wright, I. G. *Mater. High Temp.* **2003**, *20*, 375–386.

Wagner<sup>119</sup> and the interpretation of Yurek,<sup>137</sup> the parabolic oxidation rate constant for the formation of Al<sub>2</sub>O<sub>3</sub> can be related to the solid state diffusion constant by the following equation for Al<sub>2</sub>O<sub>3</sub>:

$$k_p = \frac{1}{2} \int_{P''_{O_2}}^{P'_{O_2}} [3/2D_{Al} + D_O] d \ln P_{O_2} \quad [3]$$

**Figure 24** Mass gain for CoCrAl and NiAl after 100 h at 1100 °C with various reactive element additions. CoCrAl data are from Figure 3 in Whittle and Stringer,<sup>1</sup> NiAl data are from Pint.<sup>12</sup>

**Figure 25** Total mass gain for Ni-25 wt% Cr alloys with various oxide dispersions added at a nominal level of 0.1 cation% after 100 h at 1000 °C. The mass gain decreased for larger cation additions. The addition of an Al<sub>2</sub>O<sub>3</sub> dispersion had little effect on the scale growth rate. Data from Pint.<sup>11</sup>

where  $k_p$  is parabolic oxidation rate constant,  $P'_{O_2}$  is the decomposition pressure of Al<sub>2</sub>O<sub>3</sub>,  $P''_{O_2}$  is the ambient oxygen pressure, and  $D_{Al}$  and  $D_O$  are the respective self diffusion coefficients for aluminum and oxygen. This equation can be greatly simplified<sup>137</sup> given the observation that the alumina growth rate is independent of oxygen content in the environment,  $P''_{O_2}$ .<sup>108</sup> Extrapolating published diffusion rates for bulk  $\alpha$ -Al<sub>2</sub>O<sub>3</sub><sup>138,139</sup> to 1200 °C, Table 4

**Table 4** Parabolic rate constants at 1200 °C calculated from diffusion data from the literature<sup>138,139</sup> and compared to measured values for RE-doped and undoped alumina-forming alloys<sup>7,127,203</sup>

Predominant diffusion pathway and species	$k_g$ ( $g^2 cm^{-4} s^{-1}$ ) at 1200 °C
<i>Calculated</i>	
Grain boundary diffusion of O	$1.4 \times 10^{-12}$
Grain boundary diffusion of Al	$1.5 \times 10^{-11}$
Lattice diffusion of O	$9.3 \times 10^{-14}$
<i>Measured</i>	
RE-doped FeCrAl	$(3.0\text{--}4.4) \times 10^{-12}$
Hf-doped NiAl	$(0.76\text{--}1.0) \times 10^{-12}$
Undoped FeCrAl, or NiAl	$(0.9\text{--}1.4) \times 10^{-11}$

shows that parabolic rate constants can be calculated which are of the same order of magnitude as those measured.<sup>140</sup> A recent literature review concluded that diffusion in  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> is not fundamentally well understood, making it difficult to correlate diffusion data with oxidation data.<sup>141</sup>

#### 1.24.4.2 Mechanism

While there was some confusion about the growth mechanism of Al<sub>2</sub>O<sub>3</sub> scales in the 1980s, the issue seems to be largely settled today. There were several complicating issues. First, Pt does not wet the surface of  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> (based on work with Pt photolithographic markers<sup>142</sup>). Thus, traditional inert Pt markers used to determine the scale growth mechanism floated on the alumina scale surface whether the scale grew inward or outward. In all cases, the markers showed inward growth.<sup>61,143</sup> For Cr<sub>2</sub>O<sub>3</sub> scales, inert markers showed a predominant Cr outward growth without RE dopants and predominantly O inward growth with RE dopants and this was confirmed, without controversy, using <sup>18</sup>O tracer experiments.<sup>144,145</sup> Second, the transient, cubic Al<sub>2</sub>O<sub>3</sub> phase formation confused some of the early <sup>18</sup>O studies.<sup>101,146</sup> The issue was later clarified, showing that  $\theta$ -Al<sub>2</sub>O<sub>3</sub> scales predominantly grow by an Al outward mechanism,<sup>104</sup> which is intuitive given their morphology<sup>147</sup> (Figure 18(b)). Third, unlike Cr<sub>2</sub>O<sub>3</sub>, there is no distinct difference between undoped and RE-doped  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>, both show some growth by inward O diffusion. With RE-doping, the outward Al transport is diminished and the scale grows predominantly by inward transport. This has been shown by several <sup>18</sup>O tracer studies.<sup>134,148–153</sup> An example of the tracer profiles is shown in Figure 26. The <sup>18</sup>O tracer was used first followed by <sup>16</sup>O. The first stage was 20 min at 1200 °C to ensure that the scale was

100%  $\alpha$ -Al<sub>2</sub>O<sub>3</sub>.<sup>150</sup> In the undoped scale (Figure 26(a)), the <sup>16</sup>O is enriched in both the inner and outer scale indicating both Al and O transport. With the addition of Zr, only a minor <sup>16</sup>O peak was observed at the specimen surface. A stronger <sup>16</sup>O peak was observed underneath the outer <sup>18</sup>O peak indicating predominantly inward O boundary transport.

The explanation for the RE effect on transport has long been thought to be the segregation of RE ions to scale grain boundaries in both alumina and chromia scales.<sup>8,154–157</sup> Segregation of dopant ions is commonly observed in bulk alumina because of the low solubility of many cations in the closed-packed  $\alpha$  lattice.<sup>158</sup> Examples of Y and Ti grain boundary segregation are shown in Figure 17. The mechanism by which RE ions inhibit cation transport could be blocking or site competition or a space charge effect.<sup>159</sup> However, the RE valence has not been shown to be an important variable.<sup>135</sup> A dynamic blocking mechanism was suggested, where large, slow-diffusing RE ions on the boundaries inhibit the diffusion of Al.<sup>8</sup> This mechanism is based on the observed outward transport of RE dopants during oxidation. Figure 27(a) shows a schematic of this phenomenon which is even observed on oxide-dispersed alloys like PM2000. After extended times at temperature, RE-rich oxide particles nucleate at the metal–oxide interface and grow during exposure.<sup>8,135,160</sup> Figures 27(b) and 27(c) show an example at 1100 °C where the faceted Y<sub>3</sub>Al<sub>5</sub>O<sub>12</sub> particles at the gas interface increase in volume with time and do not just coarsen. This mechanism explains why smaller dopants, Ti, Nb, and Ta, segregate to  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> grain boundaries but do not have the same effect on the scale growth rate as larger RE dopants.<sup>135</sup> These smaller ions rapidly diffuse outward and thus do not effectively inhibit Al boundary transport.

Recently, there has been renewed interest in studying the effect of RE dopants on diffusion and sintering in bulk ceramics<sup>161,162</sup> because of the observation that RE dopants like Y and La strongly improve the tensile creep strength of polycrystalline alumina.<sup>163</sup> The boundary electronic structure model proposed as an alternative to a simple dopant ion sized model to explain the behavior of various dopants<sup>164</sup> may be relevant to the effect of RE dopants on scales. Similar to results for bulk ceramics, an increase in the creep resistance of Hf-doped alumina scales has recently been demonstrated.<sup>165</sup>

As mentioned previously, the O and/or Al transport is likely along the scale grain boundaries because bulk diffusion rates in  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> are too slow to

**Figure 26** Secondary ion mass spectroscopy (SIMS) sputter depth profiles of 100%  $\alpha$ - $\text{Al}_2\text{O}_3$  scales formed isothermally at 1200 °C after 20 min in  $^{18}\text{O}$  and 40 min in  $^{16}\text{O}$  on (a) undoped NiAl and (b) NiAl + 0.11%Zr. Data from Pint *et al.*<sup>150</sup>

account for the observed growth rates. **Figure 17** shows a typical cross-section of an alumina scale where very few dislocations or other defects were observed that might accommodate ionic transport. Atkinson and coworkers<sup>166</sup> calculated that a high dislocation density was needed for dislocation transport through the grains. It could be argued that the dislocations were present at a temperature but were annihilated during cooling.<sup>141</sup> However, the cooling rate for the thin scale is rapid which would not support this hypothesis. Experimental work has also indicated that, rather than neutral species, transport in alumina scales is via charged ions, that is,  $\text{O}^{-x}$  or  $\text{Al}^{+y}$ , as applied voltages have been shown to alter the

scale growth rate<sup>167–169</sup> and electrical properties measurements indicate that  $x$  is  $\sim 2$ .<sup>170</sup>

A final point about scale growth is that there is now considerable interest in studying scale growth stresses, particularly with the advanced characterization techniques now available for *in situ* measurements.<sup>124,165,171–174</sup> These *in situ* results are considerably better than measuring the stress after cooling to room temperature by photostimulated luminescence and attempting to separate the growth stress from the thermal stress.<sup>175,176</sup> This recent *in situ* work has confirmed the observation that these growth stresses can be tensile,<sup>171,172</sup> rather than the common assumption of compressive growth stresses.<sup>177</sup>

**Figure 27** (a) Schematic representation of the outward diffusion of RE ions from oxide particles in the substrate to incorporation in the scale.<sup>8</sup> (b) and (c) show plan view SEM secondary electron images of the scale formed on PM2000 (ODS FeCrAl) after exposures in air at 1100 °C for (b) 2000 h and (c) 10 000 h.<sup>12</sup> The size and volume fraction of Y-rich oxide particles such as Y<sub>3</sub>Al<sub>5</sub>O<sub>12</sub> (YAG) has increased with exposure time. Titanium, also present in the alloy, is highly enriched at the gas interface.

The stresses can also decay with time as they are accommodated by substrate or scale creep.<sup>165</sup> Nevertheless, these stresses are generally <10% of the thermal stresses generated on cooling due to the CTE mismatch between metal and scale (see [Section 1.24.4.4.4](#)). Thus, they are often ignored when calculating the effect of stress on adhesion, eqn [1].<sup>19</sup>

### 1.24.4.3 Morphology

**Figures 28 and 29** give some examples of typical scale morphologies on alumina-forming alloys that do not form a base metal transient oxide and are commonly observed in the literature.<sup>7,135,178–181</sup> The surface morphology of transient cubic aluminas was shown in [Figure 18](#). Without a RE addition, undoped  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> often shows a wrinkled morphology with oxide whiskers at the gas interface<sup>7,117,143,178–181</sup> which hint at the outward transport of Al. As alumina scales are usually thin, the original surface roughness

(e.g., level of polishing for laboratory specimens) often affects the morphology.<sup>181</sup> At higher magnification, fine ridges can be seen that also suggest outward transport ([Figure 28\(a\)](#)). (These ridges are not the same as the ridges on  $\beta$ -NiAl formed by the  $\theta$ - $\alpha$  phase transformation.<sup>102</sup>) Undulations of the undoped oxide scales also occur on FeCrAl and Fe(Al), sometimes accompanied by equivalent deformation of the underlying metal but also due to the formation of interfacial voids.<sup>7,182–187</sup> The undulations are not found when undoped FeCrAl substrates have low S contents<sup>185</sup> or an Al<sub>2</sub>O<sub>3</sub> oxide dispersion is added ([Figure 29\(a\)](#)).<sup>187,188</sup> These differences suggest that the interfacial strength or mechanical properties of the oxide and scale may control this phenomenon.<sup>188</sup> In the cross-section, the scale typically has an equiaxed grain structure with or without wrinkles ([Figure 29\(a\)](#)).

With a RE addition, the surface ridges and whiskers are not present, indicative of the RE's role in

**Figure 28** SEM secondary electron images of the  $\alpha$ - $\text{Al}_2\text{O}_3$  scale formed on undoped FeCrAl at 1200 °C in dry flowing  $\text{O}_2$ . (a) Plan-view image of undoped FeCrAl after 2 h and (b) cross-section of the scale formed on  $\text{Al}_2\text{O}_3$ -dispersed FeCrAl after 100 h. In (a), the ridges can be referred to as intrinsic ridges to differentiate them from the extrinsic ridges formed on NiAl due to the alumina phase transformation. Adapted from Pint, B. A. Unpublished oxidation data, ORNL, Oak Ridge, TN, 1994–2008.

(a)  $\text{Al}_2\text{O}_3$ , (b)  $\text{Ho}_2\text{O}_3$ , and (c)  $\text{Er}_2\text{O}_3$ . Adapted from Pint, B. A. Unpublished oxidation data, ORNL, Oak Ridge, TN, 1994–2008; Pint, B. A.; Alexander, K. B. *J. Electrochem. Soc.* **1998**, *145*, 1819–1829. Arrows in (a) indicate internal voids.<sup>186</sup>

suppressing outward Al transport.<sup>148–153</sup> As shown in **Figure 27**, instead of ridges, fine RE-rich oxide particles form on the surface. Additions such as Ti will tend to make the surface grains more rounded and

less angular.<sup>135,189</sup> The most distinctive RE effect on morphology is on the grain structure where the change in growth mechanism results in a columnar grain structure with fine equiaxed grains near the gas interface.<sup>178</sup> In many alloys, the layer of equiaxed grains does increase in thickness with time because of the small amount of outward Al transport.<sup>190</sup> However, the scale thickening is predominantly due to an increase in the length of the columnar grains. Unlike some studies showing no texture, an x-ray pole figure on the scale formed on PM2000 at 1200 °C showed a preferred growth direction.<sup>191</sup> The grain structure of RE-doped  $\alpha$ - $\text{Al}_2\text{O}_3$  is remarkably similar independent of the RE type and substrate, that is, M–Al or M–Cr–Al, likely because the scales on all these substrates grow by a similar mechanism. Some less common RE dopants are shown in **Figure 29** to illustrate that a wide range of dopants produce similar effects. Varying the type and amount of dopant can alter the size and structure of the columnar grains.<sup>192</sup>

#### 1.24.4.4 Adhesion

The most critical performance issue for alumina-forming alloys in long-term high temperature applications is scale adhesion. Adherent scales grow with parabolic (or even cubic) kinetics which results in very slow Al consumption rates from the substrate. However, when the scale spalls, the oxide must regrow or heal the spalled region, resulting in a significant increase in the rate of Al consumption due to the initial high rate of oxidation. As described in **Section 1.24.1**, the major cause of scale spallation is the thermal or cooling stress due to the CTE mismatch ( $\Delta\alpha$ ) between the substrate and oxide, see **eqn [1]**. An additional issue is the formation of voids or other defects at the exposure temperature that lead to decohesion. Without defects, the scale will eventually reach a critical thickness,  $\zeta_f$ , where the strain energy ( $W^*$ ) is sufficient to cause spallation, **eqn [2]**. Defects will decrease the interfacial adhesion resulting in failure at a lower scale thickness.

For undoped alumina-formers, void formation at the metal–alumina interface is typically one of the critical issues that determines adhesion. Provenzano and coworkers<sup>193</sup> found in CoCrAl compositions that the interfacial void area increased with temperature from 700 to 1000 °C. Typically, these voids are thought to be formed by a Kirkendall-type mechanism either due to diffusion in the alloy or the oxide or both. Because of the outward transport of Al in the undoped scale, a counter current vacancy flux moves

towards the metal-scale interface. Also, because of the faster undoped scale growth rate, there is increased diffusion in the substrate with Al diffusing to the interface and other elements moving in the opposite direction. Contributing to the nucleation or growth of interfacial voids may be surface-active interstitial impurities such as S,<sup>186,194</sup> which will be discussed further in Section 1.24.4.4.2.

One problem with discussing scale adhesion is that it is difficult to quantify.<sup>195,196</sup> A well-formed scale is more tenacious than most epoxies used in quantifiable pull tests with an interface fracture toughness of  $>90$  MPa.<sup>197</sup> Specimen mass gain curves can be used with a decrease in mass suggesting spallation. However, consider some NiCrAl alloy examples in Figure 30. The specimens that spall and rapidly lose mass are obvious but a higher specimen mass gain does not necessarily indicate a more adherent oxide. A higher mass gain could indicate a faster growing oxide coupled with minor spallation. The lower mass gain for NiAl + Hf is due to a thinner, adherent oxide. Furthermore, some oxides remain attached but are friable and therefore not protective,<sup>198</sup> resulting in a false indication of adhesion. Many early RE optimization studies relied on a relatively short term cyclic oxidation data to conclude that a certain composition was superior.<sup>131,133</sup>

A more absolute way of quantifying scale adhesion is cyclically testing specimens through the steady-state oxidation period until they reach breakaway oxidation (see Section 1.24.5). Figure 31 shows the time to

**Figure 30** Specimen mass change of various Ni-20Cr-19Al alloys during 1 h cycles at 1100 °C in dry flowing O<sub>2</sub>. The codoping of Y and Hf produced better scale adhesion compared to Hf or Y additions alone. Data from Pint<sup>12</sup> and Pint *et al.*<sup>94</sup>

breakaway for various FeCrAl models and commercial alloys, all with  $\sim 10\%$  Al. In order to accelerate the test, 1 h cycles were used at 1200 °C. The time has been normalized to a 1.5 mm thick specimen. Thus, all the specimens begin with a similar Al reservoir and the rate of scale growth and adhesion are thus key parameters in determining lifetime (see Section 1.24.5). An undoped wrought FeCrAl specimen, which spalls readily during thermal cycling, had a lifetime of only  $\sim 300$ , 1-h cycles. From Figure 31, it is obvious that RE additions play a critical role in increasing scale adhesion and thus increasing life.

#### 1.24.4.4.1 Reactive elements

The main beneficial effect of RE additions (e.g., Y, Zr, Hf, La, Ce) on alumina-forming alloys is the improvement in scale adhesion. Figure 31 shows that the addition of 0.08 Y increased the lifetime of FeCrAl by a factor of 30 compared to undoped FeCrAl. Most studies have observed a reduction in the interfacial void formation. A number of hypotheses have been proposed to explain the RE effect on void formation. Tien and Pettit<sup>143</sup> proposed that the RE dopants in the alloy formed a vacancy complex that prevented vacancies from coalescing at the metal scale interface. Using a similar logic, Kumar *et al.*<sup>199</sup> suggested that RE internal oxides in NiCrAl acted as a vacancy sink. However, there is no experimental evidence of these hypotheses. The formation of RE internal oxides or ‘pegs’ was thought to create a mechanical interlock that improved scale adhesion.<sup>61,131,132,200</sup> While a small number of

**Figure 31** Normalized time to breakaway oxidation (as an indicator of scale adhesion) for various FeCrAl alloys (see Table 2) at 1200 °C in 1 h cycles. The lifetime is normalized to a 1.5 mm thick specimen. Model wrought alloys doped with Y and Hf showed the longest lifetime. Data from Pint.<sup>12,129</sup>

pegs is likely to be beneficial in preventing interfacial (metal–scale) crack propagation, pegs are not necessary as ODS alloys achieve good scale adhesion without forming pegs. For example, the lifetimes for several ODS alloys are shown in **Figure 31**.

Another hypothesis was that the finer grained RE-doped alumina scale resulted in a more plastic oxide that accommodated the strain better.<sup>61,201</sup> Ironically, the recent work on RE-doped bulk alumina<sup>161,163,164</sup> and scales<sup>165</sup> has shown that RE-doping actually increased the creep strength by several orders of magnitude. The change in mechanical response of the oxide scale with Y doping can explain the higher residual stresses measured in Y-doped alumina scales.<sup>176</sup> Weaker, undoped scales can wrinkle to accommodate the growth stress at temperature.

One of the issues that confounded potential hypotheses to explain the role of RE additions was the reported benefit of *any* oxide dispersion, including  $\text{Al}_2\text{O}_3$  on scale adhesion.<sup>143,202</sup> This result could not be repeated in more recent work on  $\text{Fe}_3\text{Al}$ ,  $\text{NiAl}$ , or  $\text{FeCrAl}$ .<sup>135,188,203</sup> No benefit on scale adhesion, growth rate, or scale morphology was observed with only an  $\text{Al}_2\text{O}_3$  dispersion. In **Figure 31**, an  $\text{Al}_2\text{O}_3$  dispersion reduced the lifetime from 300 h for wrought undoped  $\text{FeCrAl}$  to 70 h.

A current interpretation<sup>8</sup> of the role of RE additions on scale adhesion involves several issues: (1) the inhibition of outward Al transport decreases the counter vacancy flux to the interface, (2) the segregation of RE ions to the interface decreases the interfacial energy ( $\gamma_{\text{int}}$ ), thereby increasing the critical scale thickness<sup>7,8,204</sup> (see eqn [2]), and (3) the RE addition prevents the interfacial segregation of S which has a detrimental effect on void growth. The observed outward flux of RE ions from the alloy into the scale results in RE ions segregated at the metal–scale interface.<sup>7,8</sup>

Mechanistically, the role of RE additions may be resolved, but, practically the issue of optimizing that benefit has not. The type of dopant, the amount, and the method of addition has still not been completely resolved. However, a few issues have been clarified. Surface doping with RE oxide coatings or ion implantation does not produce optimal benefits.<sup>6,118,205</sup> Alloy additions and oxide dispersions are clearly superior. Effective RE dopants have two qualities: large ion size and high oxygen affinity.<sup>135</sup> To avoid the issue of dopant solubility, which affects internal oxidation and other issues, a screening test was performed on various dopants added as oxide dispersions. **Figure 32** shows the 1200 °C, 1 h cycle

**Figure 32** Normalized time to breakaway oxidation (as an indicator of scale adhesion) at 1200 °C in 1 h cycles for various oxide (VN for V,  $\text{BaTiO}_3$  for Ba) dispersions (0.025–0.2 cation% additions) in  $\text{Fe-20Cr-10Al}$ . Lifetimes were normalized to a 1.5 mm specimen thickness. Low lifetimes for diamonds (Sc, Ce, Eu, and Yb) were attributed to over-doping with 0.2% additions. In general, all the lifetimes are somewhat lower than in commercial ODS alloys because of the laboratory processing. Data from Pint.<sup>11,12</sup> and Pint and Alexander.<sup>135</sup>

normalized lifetime for various dopants added as 0.2 cation% oxide dispersion additions to  $\text{FeCrAl}$ . (In general, the lifetimes for these laboratory-made alloys were not as good as that of the higher-quality commercial alloys (**Figure 31**).) There is a weak correlation between lifetime and larger ion size with many dopants not fitting this explanation. Several large ions, such as In, Te and Bi, have low oxygen affinity and never become incorporated into the oxide. Dopants such as Sc, Yb, Ce, Hf, La, and Eu produced negative effects with 0.2% additions associated with over-doping.<sup>135</sup> The data points for Hf and La, two of the highest lifetimes, were additions of 0.05%.

For alloy additions, **Figure 31** suggests that the best RE dopant is Y (compared to Hf, Zr, or mischmetal, a combination of Ce, La, and Nd). However, there was a considerable difference in lifetime between 0.08 and 0.035 Y additions. **Figure 33** shows lifetime as a function of specimen thickness for several Y additions. It is interesting to note that the lower Y contents, which would result in less internal oxidation, produced lower lifetimes than the specimens with 0.08% Y. A wider range of Y additions needs to be studied to resolve this issue and identify an optimum for lifetime. However, given the weak correlation with specimen thickness, these results suggest that the thicker specimens may become depleted in Y due to

**Figure 33** Time to breakaway oxidation (i.e., Fe-rich oxide formation) at 1200 °C using 1 h cycles for various RE-doped FeCrAl alloys (dopant contents in ppm) as a function of specimen thickness. For both Y-doped and co-doped (Y and Hf) alloys, there is a decrease in lifetime with very low RE additions. Data from Pint.<sup>12</sup>

spallation and not get as full a benefit as with higher Y additions. A similar result has been observed with RE doping in NiCrAl coatings.<sup>206</sup>

**Figure 30** shows better spallation resistance for a NiCrAl with both Y and Hf compared to Y or Hf alone. **Figures 31 and 33** show the highest lifetimes for a combination of Y and Hf. This so-called co-doping results in low scale growth rates, minimal internal oxidation, and more optimal performance. Commercially, some alloys contain two or more dopants such as NiCrAl alloy 214 (Y and Zr), SX superalloys 1487 and N5+ (Hf and Y), and Aluchrom YHf (Y, Zr, Hf, and Ti) (**Tables 1 and 2**). A Pratt & Whitney NiCoCrAl coating (PWA286) also contains Y and Hf.<sup>207</sup> Co-doped alloys rely on a higher solubility dopant (Hf or Zr) along with lower levels of the low solubility Y dopant. Again, dopant depletion can be an issue because the lowest level of Y and Hf dopant did not produce the longest lifetime in a model FeCrAl alloy (**Figures 31 and 33**). Co-doping levels in model alloys were selected to match the alloy interstitial levels to achieve a  $[Y]/[S] > 1$  and a  $[Hf]/[C] > 1$ .<sup>129</sup> This interstitial-dopant ratio strategy was originally proposed by Sigler.<sup>208</sup> In commercial alloys, the interstitial levels are higher than in the laboratory, which may require slightly different doping strategies.<sup>10</sup> Trying to target narrow composition windows is probably not realistic for commercial production, particularly considering that a co-doped alloy with a  $Y/S < 1$  will have very poor performance lifetime, for example, FeCrAl with 0.018Hf(+Y) in **Figure 31**.

#### 1.24.4.4.2 Interstitials (S, C, etc.)

Identifying the detrimental role of S, and possibly other interstitials, has caused a major shift in the thought process on scale adhesion of alumina-forming alloys in the past 25 years.<sup>28,185,204,208–216</sup>

The early work by Smeggil and Smialek on NiCrAl and later on FeCrAl has resulted in almost every commercial high temperature alloy being produced with  $< 5$  ppm S, **Table 2**. While an early hypothesis<sup>217</sup> suggesting that S could explain all RE effects was disproved,<sup>8,204</sup> the current mechanistic understanding is that S segregates to the metal–scale interface thereby increasing the interface energy, which in turn increases the formation of interfacial voids and weakens the interface.<sup>186,194,218,219</sup> Sulfur segregates to all free surfaces<sup>220</sup> and alloy grain boundaries; thus, it is not surprising that a high S content in nano-grained FeCrAl did not have a detrimental effect on alumina scale adhesion.<sup>221</sup> The large number of alloy grain boundaries provided alternative locations for S segregation besides the metal–scale interface.

An alternative explanation, that other interstitial elements besides S, such as Na and Ca, has been proposed.<sup>222</sup> However, a follow-up study by Smialek<sup>223</sup> which examined 41 elements in a Ni-based superalloy found that hydrogen annealing of superalloys, which improved alumina scale adhesion, primarily lowered the S and C contents. It has been suggested that La additions to superalloys was beneficial in countering a detrimental effect of P.<sup>224</sup> However, a study of Ni–7Cr–13Al + Y alloys with intentional P additions (70 ppm) showed no effect on scale adhesion during 1 h cyclic testing at 1100 °C.<sup>12</sup>

A common RE–S explanation is that RE dopants ‘getter’ S away from the metal–scale interface by forming RE–S compounds.<sup>210</sup> However, this mechanism has not been proven for ODS alloys (which contain high S levels, **Table 2**) where dispersoids did not contain S and S was not found segregated to the dispersoid–alloy interface.<sup>8</sup> The observation of a Y–S compound<sup>225,226</sup> is not proof of a gettering mechanism, only that Y forms a stable sulfide. A segregation-based RE mechanism suggests that RE ions segregate to the metal–scale interface and lowers the energy such that S segregation is no longer thermodynamically favorable.<sup>8</sup> Whether this involves site competition for segregation or another mechanism is not known. Nevertheless, there is a clear relationship where the Y/S ratio needs to be greater than unity for good scale adhesion in FeCrAl and NiCrAl.<sup>28,129</sup>

#### 1.24.4.4.3 Precious metals

Alumina scale adhesion has been improved by Pt and other Pt group metals (PGMs).<sup>79,84–86,227–229</sup> The majority of observations have been for Ni-based alloys and coatings, especially  $\beta$ -NiAl. Pt additions also have been used to improve the performance of CoCrAlY coatings.<sup>227</sup> While the effect of Pt on adhesion is similar to RE additions as both are likely to lower the metal–scale interface energy, the mechanism is quite different as  $\sim 2$  at.% Pt or Ir is needed as an alloy addition to improve adhesion. Also, Pt does not alter the scale growth rate and does not become incorporated into the alumina scale or segregate to scale grain boundaries, even on Pt–Al alloys.<sup>230</sup>

There is some disagreement about the effect of Pt additions in FeCrAl-based alloys. One study suggested that PGM additions benefited scale adhesion on FeCrAl.<sup>229</sup> However, that result could not be reproduced with 0.1 or 3 at.% Pt additions.<sup>12</sup> Unlike in Ni-based compositions, the formation of a Pt-rich phase in FeCrAl + 3Pt, likely due to limited solubility of Pt in ferrite, may explain the lack of benefit compared to Ni- and Co-based alloys and coatings.

#### 1.24.4.4.4 Role of CTE

Thermal expansion mismatch between the metal and scale is a critical factor in understanding the oxidation resistance of various alumina-forming alloys. The effect is most evident in the Fe–Al system because of the very high CTE of the aluminide phases, particularly  $\beta$ -FeAl.<sup>52,128,231–233</sup> The difference in CTE can explain the scale spallation problems of RE-doped aluminides compared to ferritic FeCrAl and Fe(Al) alloys. The effect in RE-doped Fe–Al alloys can be quantified to a certain extent by using an approximation of the critical scale thickness,  $\xi_f$ , from eqns [1] and [2]:

$$\xi_f \propto (\Delta T \Delta \alpha)^{-2} \quad [4]$$

Above this thickness, the strain energy in the scale exceeds the interface strength and spallation occurs. Assuming that the Al content does not affect the interface or oxide properties, if  $\xi_f = 10 \mu\text{m}$  for FeCrAl, then it is only  $1 \mu\text{m}$  for  $\beta$ -phase Fe–40Al and  $2 \mu\text{m}$  for Fe<sub>3</sub>Al.<sup>233</sup>

Figure 34 gives some typical mean CTE values for alumina-forming alloys as a function of temperature. The values for NiAl, FeCrAl and Ni–22Al–5Pt are all remarkably similar at 1000–1200 °C and all these materials have the lowest CTE mismatch with

**Figure 34** Mean coefficient of thermal expansion as a function of temperature for several Ni- and Fe-based alloys (see Table 2) showing the difference between these metals and alumina. Data from Haynes *et al.*,<sup>30</sup> Pint *et al.*,<sup>82</sup> Wright *et al.*,<sup>232</sup> and Pint *et al.*<sup>233</sup>

$\alpha$ -Al<sub>2</sub>O<sub>3</sub>. Alloys that have a phase transformation such as NiCoCrAlY or  $\beta$ -FeAl have much higher CTE than the materials that remain a single phase across the 25–1200 °C temperature range.

For Ni-based alloys, it is difficult to draw an exact correlation between CTE mismatch and scale adhesion, again because it is difficult to quantify scale adhesion. One criterion used previously for lifetime modeling was the time to zero specimen mass gain,  $t_z$ , in a cyclic oxidation test.<sup>234</sup> For example, in Figure 31 the  $t_z$  for Hf-doped NiCrAl would be  $\sim 85$  h and  $\sim 425$  h for Y-doped NiCrAl. In Figure 35, the CTE mismatch is plotted versus  $t_z$  at 1150 °C for several Ni-based alloys.<sup>30</sup> The general trend in the data is that a smaller  $\Delta\alpha$  results in a longer  $t_z$ . The various NiCrAl and NiCoCrAlY compositions have a higher CTE and spall more readily. One complicating issue for this type of plot is that RE additions have a strong influence on scale adhesion (and thus  $t_z$ ) but have no effect on CTE.<sup>30</sup> Therefore, the horizontal arrows show the increase associated with RE-doping or RE optimization (in the case of NiCrAlYHf). The dashed line represents an assumed optimum for RE doping. (Note that the 2000 h value for Hf-doped NiAl was an approximation, the mass gain did not reach zero after 2000 h cycles at 1150 °C, although it was decreasing towards zero.<sup>12</sup>)

#### 1.24.4.4.5 Role of substrate strength

One of the alloys that does not fit the trend in Figure 35 is the single-crystal (SX) superalloy, N5, which contains both Y and Hf. There are two possible

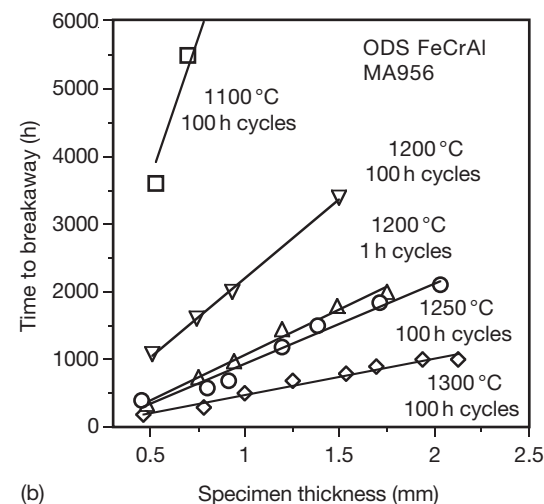

**Figure 35** Difference in CTE between the alloy and alumina at 1150 °C for various Ni-based alloys (see Table 2) plotted versus the number of 1 h cycles to zero mass gain at 1150 °C. The number of cycles reflects the relative scale adhesion of these materials. Intermetallic alloys have much lower CTE values than the multiphase NiCrAl alloys that undergo phase transformations between RT and 1150 °C. Adapted from Haynes, J. A.; Pint, B. A.; Porter, W. D.; Wright, I. G. *Mater. High Temp.* **2004**, 21, 87–94.

reasons for this deviation, one is that the spallation of the transient oxide on this alloy increases the specimen mass loss but does not actually reflect the adhesion of the alumina scale. The other possible reason is that this very strong SX substrate does not accommodate the stresses in the scale (e.g., by creep) like a weaker substrate, such as NiAl, resulting in earlier scale spallation.<sup>235,236</sup>

A substrate creep strength hypothesis has been used to explain the decreased alloy lifetimes of ODS FeCrAl alloys compared to weaker wrought FeCrAlY or Fe(Al)Y (Figures 31 and 36(a)).<sup>233</sup> One exception to this negative effect of alloy strength is the commercial FeCrAl alloys APM and APMT.<sup>233</sup> With the addition of Mo and lower Cr content, APMT has a higher creep strength than APM<sup>237</sup> but essentially no decrease in lifetime (Figure 36(a)). However, APMT also contains Y and Zr so that RE optimization compared to APM may be responsible for maintaining the cyclic oxidation lifetime.

Substrate strength also affects the performance of foil specimens. In this case, the thin metal section deforms due to stresses in the oxide and little scale spallation occurs in most cases. The compressive stress generated in the growing oxide can cause the foil to lengthen due to the tensile stress in the adjacent metal. This increase in length has been

**Figure 36** Time to breakaway oxidation (i.e., Fe-rich oxide formation) as a function of initial specimen thickness (a) at 1200 °C using 1 h cycles for various FeCrAl and Fe-Al alloys (b) for alloy MA956 under various cyclic conditions (see Table 2 for compositions). Data from Pint<sup>12</sup> and Pint *et al.*<sup>233</sup>

characterized because it can be detrimental to the performance of FeCrAl catalyst supports.<sup>238</sup>

In general, it is difficult to quantify the mechanical effects of typical alumina-forming alloys because the tensile properties and creep (primary, as well as steady-state) rates are not commonly measured at the temperatures relevant for high temperature oxidation.<sup>187</sup>

#### 1.24.4.4.6 Effect of cycle frequency

A final note about adhesion is that increasing the cycle frequency, that is, reducing the time per cycle usually decreases scale adhesion by increasing the number of

thermal cycles per time period.<sup>15,198,234,239</sup> Figure 36(b) gives examples of the time to breakaway oxidation for ODS alloy MA956 under various cyclic conditions. Of course increasing the temperature decreases the lifetime using 100 h cycles at 1200–1300 °C. However, increasing the cycle frequency from 100 to 1 h per cycle at 1200 °C, produced a reduction in lifetime similar to increasing the test temperature by 50 °C. Figure 37 gives an example for FeCrAlY where during 100 h cycles to a total time of 5000 h cycles, virtually no scale spallation occurred. However, in 1 or 2 h cycles, spallation began after a few hundred hours. One-hour cycles are used in lifetime testing to accelerate the experiment by inducing scale spallation more quickly.

Exceptions to the inverse relationship between cycle frequency and scale adhesion were observed for some Ni-based superalloys.<sup>15</sup> This behavior was attributed to the spallation of transient scale during longer cycles but could also be due to the time-dependent growth of defects such as interfacial voids. In short cycles, the defect may never reach the critical size necessary to cause spallation or only cause small areas to spall. Longer cycles, with long holds at temperature, may allow defects to grow to a sufficient size or accumulate such that scale spallation occurs over large areas.

**Figure 37** Specimen mass change for FeCrAl-0.08Y as a function of total exposure time for various cycle frequencies of 1–100 h per cycle. In 100 h cycles, very little spallation was observed but reducing the cycle time increases the number of thermal cycles and increases the amount of spallation, particularly for 1 and 2 h cycles. Data from Pint<sup>12</sup> and Pint *et al.*<sup>15</sup>

#### 1.24.4.5 Internal Oxidation

The formation of oxide (or, more generally, any oxidation reaction product) within the alloy, beneath the external scale, is generally regarded as detrimental because it can degrade the mechanical properties of the substrate and interfere with the long-term chemical or mechanical stability of the protective external scale. For example, an internal oxide can help to nucleate a crack in the substrate. As also described previously (Section 1.24.4.1), internal oxidation generally increases the overall oxidation rate and can serve as fast transport paths for oxidants. The issue of internal oxidation of Al could be related to insufficient Al content to form an alumina scale, which essentially is a problem of low Al content alloys and/or alloys with poor selective oxidation.

Internal oxidation behavior has been studied on dilute M–Al alloys to understand the transition from internal to external oxidation. As oxidation is a diffusion controlled process, parabolic kinetics are generally observed.<sup>240,241</sup> The internal versus external oxidation condition given by Wagner<sup>240</sup> suggested that the oxidant solubility and diffusivity in the alloy were critical. Wolf and Evans<sup>242</sup> showed that the internal oxidation rate of Ni–Al alloys was nearly independent of the  $pO_2$  in the environment. Whittle *et al.*<sup>243</sup> found that the internal formation of  $Al_2O_3$  in dilute Ni–Al alloys accelerated O diffusion within the alloy, likely at the  $Al_2O_3$  precipitate–metal interface. This could explain the faster oxidation kinetics of dilute Ni–Al alloys compared to unalloyed Ni.<sup>244</sup>

In alloys with sufficient Al to form an external alumina scale, internal oxidation of Al has been observed in Fe(Al) + 0–5Cr alloys at 800–1000 °C in air.<sup>93</sup> Internal oxides as well as nitrides were observed on undoped alloys with defective alumina scales. It was concluded that the defective scale allowed N permeation through the scale into the substrate. The less-stable AlN precipitates were displaced by more-stable oxides and nitride formation moved further (deeper or laterally) into the substrate with time. The high mass gains (with linear kinetics) for the undoped ferritic Fe(Al) alloys are shown in Figure 15. Figure 15 also shows that internal oxidation did not occur in air for undoped Fe–20Cr–10Al.

Internal oxidation of other alloy elements may occur, typically only those with a higher affinity for O than Al such that oxidation will occur below the Al/ $Al_2O_3$  equilibrium  $pO_2$  at the metal–scale interface. All RE additions fall into this category.<sup>135</sup> The issue of RE internal oxidation has already been

**Figure 38** Light microscopy of polished cross-sections of FeCrAl + 0.038(Y,Hf) after oxidation in laboratory air for (a) 5000 h at 1000 °C and (b) 100 h at 1300 °C.<sup>12</sup> More internal oxidation occurred at low temperature than at high temperature where a much thicker external oxide formed.

discussed in terms of minimizing the internal oxidation by reducing the RE addition (e.g., [Figure 23](#)). The effect of oxidation temperature on internal oxidation is complicated by the effects of solubility and diffusivity.<sup>240</sup> The solubilities and diffusivities of both O and the RE increase with temperature but at different rates. An example of the effect of temperature on internal oxidation is shown for FeCrAlYHf in [Figure 38](#). Over the range of 1000–1300 °C, it is difficult to make direct comparisons. However, relative to the external scale thickness, the internal attack at 1000 °C was deeper than at 1300 °C. The solubility of the particular RE addition in the alloy also could play a factor in the temperature effect.

For  $\gamma$ - $\gamma'$  NiPtAl alloys, the addition of Pt decreased the internal oxidation of Hf.<sup>80</sup> The effect was particularly strong with 10–15%Pt and Hf levels up to 0.4%. This Pt effect was attributed to Pt suppressing the Hf activity;<sup>80</sup> however, it could also be an effect of Pt on the O solubility.

#### 1.24.4.6 Comparison of Fe-, Ni-, and Co-Based Alumina Forming Alloys

Only a few authors have explicitly examined the differences in oxidation behavior due to the base metal.<sup>60,95</sup> In general, FeCrAl alloys are the best alumina-formers because they are single-phase, have a lower CTE, faster diffusion in the alloy (due to their bcc structure) and lower O solubility. This combination of diffusivity and solubility results in

lower Cr and Al additions needed to form alumina and better alumina adhesion. With two-phase alloys, the Al-poor phase will tend to form more base-metal oxide. Furthermore, alloy phase transformations typically increase the CTE. The low CTE of FeCrAl results in less thermal stress which drives scale spallation. Faster Al diffusion in the alloy minimizes Al concentration gradients in the alloy and decreases the critical Al content needed to form alumina. The rapid growth of FeO ( $\sim 10^6$  times faster than  $\text{Al}_2\text{O}_3$ ) results in more catastrophic failure at the end of life compared to NiCrAl (NiO forms  $\sim 10^3$  times faster than  $\text{Al}_2\text{O}_3$ ), however, the other factors tend to outweigh this problem.<sup>60</sup>

Several studies agree that the oxidation behavior of CoCrAl alloys are decidedly inferior to NiCrAl or FeCrAl.<sup>60,245</sup> For the formation of an alumina scale, Co-based alloys require higher Cr and Al contents because of the rapid growth of CoO ( $\sim 10^5$  times faster than  $\text{Al}_2\text{O}_3$ ) and the relatively low diffusivity in the alloy compared to Ni ( $\sim 10^2$  slower) and Fe-based ( $\sim 10^3$  slower) alloys.<sup>60</sup> In cyclic oxidation testing, CoCrAl alloys can be improved by RE additions.<sup>132,245,246</sup> However, their cyclic oxidation resistance is inferior to NiCrAl. The main interest for Co-based alumina-forming materials appears to be as coatings for Co-based alloys.

#### 1.24.5 Breakaway Oxidation

The final stage of oxidation is breakaway which is characterized by rapid oxidation due to the depletion of Al from the substrate and the formation of faster-growing reaction products. [Figure 39](#) shows a failed specimen of FeCrAl alloy APMT cycled to failure at 1200 °C using 1 h cycles. One edge had been completely consumed by Fe-rich oxide formation. Typical of many dispersion strengthened alloys,<sup>247</sup> the center contains Kirkendall voids due to the depletion of Al. In stronger ODS FeCrAl, the voids are often perfectly round. In weaker wrought FeCrAlY, more deformation of the substrate occurs and center voids are not very evident.

The time to breakaway,  $t_b$ , is thus the useful lifetime of a component with thickness,  $d$ . It was used in several figures in the previous section ([Figures 31–33](#) and [36](#)). A common model for lifetime of Fe-based alloys is based on the Al reservoir in the component and the rate of consumption of that reservoir<sup>41,42</sup>:

$$d\rho(C_0 - C_b) = A k t_b^n \quad [5]$$

**Figure 39** Light microscopy of polished cross-sections of alloy APMT after cycling to failure in 1 h cycles at 1200 °C.<sup>12</sup> One edge has been consumed and only Fe-rich oxide remains. In the center of the specimen, large Kirkendall voids remain from the depletion of Al.

where  $\rho$  is the alloy density,  $C_0$  is the starting Al content in the alloy,  $C_b$  is the Al content where the material can no longer form a protective alumina scale,  $A$  is a constant,  $k$  is a rate constant, and  $n = 0.5$  for parabolic kinetics and 1 for linear kinetics. For FeCrAl-type alloys with  $\sim 20\%$  Cr,  $C_b$  is close to zero. With lower Cr contents,  $C_b$  increases to  $\sim 10\%$  Al in Fe–Al binary alloys.<sup>248,249</sup> This type of equation allows the lifetime to be predicted as a function of component thickness or for a thickness to be selected to achieve a desired service lifetime.

One of the key assumptions of the reservoir model is that there are no Al gradients in the substrate; this greatly simplifies behavior. It is a reasonable assumption for foil (e.g., Figure 20) and thin ( $<1$  mm) components.<sup>248</sup> However, for thicker components, Al gradients do occur and cause significant deviations in lifetime behavior.<sup>249</sup> For example, Figure 40 shows the gradients in several MA956 specimens oxidized to failure at 1200, 1250, and 1300 °C. The center of the specimen contained  $>1\%$  Al while the end of the specimen, near where the breakaway formation of Fe-rich oxide occurred, had  $\sim 0.1\%$  Al. Earlier studies suggested that  $C_b$  was a function of thickness.<sup>250</sup> While  $C_b$  effectively increases with thickness because of Al gradients in thick substrates, mechanistically, in all cases, the value of  $C_b$  at the metal–scale interface,  $C_{bi}$ , at breakaway is close to zero.<sup>249</sup>

Gradients also drive early failures in some materials (Figure 41). For Fe–17Al + Hf and NiCrAlY/Zr (alloy 214), increasing the specimen thickness resulted in virtually no increase in  $t_b$ . It was shown that Al gradients formed in Fe–17Al + Hf resulted in early failures for the thicker specimens.<sup>52,249</sup> A similar failure mechanism may occur on alloy 214,<sup>251</sup> but less characterization work was performed

**Figure 40** EPMA Al line scans from two different MA956 (ODS FeCrAl) specimens oxidized to breakaway at 1200–1300 °C and metallographically sectioned. The center scans are across the entire specimen thickness near the center of the specimen while the end scan is from an end of the specimen with distance from the edge towards the center of the specimen. Data from Pint *et al.*<sup>249</sup>

on this alloy after cyclic oxidation. Specimen geometry (e.g., corners on thin specimens) can also lead to early failure. Therefore the specimen surface area to volume also can affect lifetime and round versus flat specimens may behave differently.<sup>252</sup>

As shown for alloy 214 (Figure 41), the behavior of Ni-based alumina-forming alloys<sup>12</sup> may not be explained well by the Quadakkers reservoir model. The slower diffusion of Al in austenitic alloys and the formation of multiple phases ( $\gamma$ ,  $\gamma'$ ,  $\beta$ ) in NiCrAl alloys may result in complications that are better modeled by a diffusion based model as suggested by Nesbitt and Heckel<sup>253</sup> or the spallation-based COSP

**Figure 41** Time to breakaway in 1 h cycles at 1200 °C versus specimen thickness for various alumina-forming alloys (see [Tables 1 and 2](#)). For alloy 214 and Hf-doped Fe-17Al, there was little increase in lifetime with specimen thickness due to the formation of alumina gradients. Data from Pint<sup>12</sup> and Pint et al.<sup>233</sup>

model.<sup>17</sup> These models and Nesbitt's COSIM (Coating Oxidation and Substrate Interdiffusion Model)<sup>254</sup> are well suited for studying the behavior of NiCrAl coatings where the Al content decreases both due to oxidation and interdiffusion with the coating substrate.

As shown in [eqn \[5\]](#), the consumption side of the equality is very simplistic. Parabolic kinetics would only be observed for alloys where no spallation occurred. As shown in [Figure 41](#) and in previous figures, the nearly linear relationship between specimen thickness and  $t_b$  suggests that linear kinetics, that is,  $n = 1$ , are more relevant. However, this approximation would overestimate the Al loss at early times, when the scale is adherent and Al consumption follows parabolic kinetics. A more complicated consumption equation probably involves several time stages with different  $k$  and  $n$  values for each stage.<sup>251</sup> If a critical scale thickness could be identified to determine the change from the protective scale phase to the spallation phase (with higher Al consumption and higher  $n$ ), such a model would be more mechanistic and accurate.

Other models are available to predict lifetime. The NASA-developed COSP model uses the scale growth and spallation rates to predict lifetime.<sup>17</sup> The spallation mass loss rate is attributed to an area fraction of spallation and regrowth. This model has been applied to an extensive oxidation database of typically Ni-based and ODS FeCrAl alloys that exhibit near-linear spallation rates. However, wrought

Fe-based alloys that do not spall as orderly cannot be modeled in this manner (compare Ni-base spall behavior in [Figure 30](#) to Fe-based spallation in [Figure 37](#)). In general, measuring the residual Al content and determining the rate of Al loss in the alloy is the most accurate method of predicting lifetime.<sup>255</sup>

#### 1.24.5.1 Failure Mechanisms

In practice, two types of oxidation-induced failure can be distinguished.<sup>256</sup> A chemical failure occurs when the substrate is sufficiently depleted in Al that it can no longer form alumina. The most extreme example of such a failure is for FeCrAl(+RE) foil where no scale spallation occurs because the foil can deform and accommodate strain energy from the scale. When the foil is depleted in Al, a chromia scale has been observed to form beneath the alumina scale.<sup>257</sup> As  $\text{Cr}_2\text{O}_3$  is less stable than  $\text{Al}_2\text{O}_3$ , normally this would not be thermodynamically possible. It occurs when Al is removed from the metal and the interface oxygen potential increases allowing  $\text{Cr}_2\text{O}_3$  to form.

Prior to a chemical failure, a mechanical failure can cause a premature failure by cracking the scale and requiring reformation of alumina at a bare interface.<sup>256</sup> The mechanical failure could be due to the typical thermal stress (which can induce scale spallation), an applied stress to the component in service or a one-time upset or impact which removes the surface oxide. In this case, the  $C_b$  at failure is higher, reducing  $t_b$ .

#### 1.24.5.2 Unusual Failure Mechanisms

Some unusual circumstances can cause early failure of alumina scales. Additional oxidants (discussed in the next section) can cause early failure as will environments that can otherwise degrade the alumina scale. As mentioned previously, the formation of Al concentration gradients in the alloy will result in earlier failures. This is generally not a problem for Fe-based alloys with relatively rapid Al diffusion (e.g., flat Al profiles in [Figures 20 and 40](#)). However, it appeared to be a problem for Fe-17Al + Hf, Ni-based alloy 214 (see [Figure 41](#)) and is likely a problem for Co-based alloys. There is little data in the literature for Ni- and Co-based alloys on residual Al profiles or lifetime as a function of specimen thickness.

Another unusual failure mechanism for Fe-based alloys has been attributed to the internal oxidation of Cr carbides on alloy grain boundaries resulting in

accelerated Fe-rich oxide formation at alloy grain boundaries, sometimes called ‘broccoli’ failures because of the eruption of the voluminous Fe-rich oxide.<sup>258</sup> This type of failure is found in alloys with higher C contents but no strong carbide former, for example, Y-doped FeCrAl and Fe–Al. The problem can be eliminated by the addition of a strong carbide former such as Hf or Ti, which is a common addition in commercial alloys, **Table 2**. For example, **Figure 42** shows the mass gain of ferritic Fe–17Al alloys tested at 1250 °C to accelerate their failure. With only Y or Y and Cr additions,  $t_b$  was relatively short compared to the specimen with a Hf addition. The early failures showed broccoli failures. However, when a small amount of Ti or Hf was added, the lifetime increased dramatically.

### 1.24.5.3 Strategies for Extending Lifetime

One goal of alloy development is to design alloys with longer lifetimes. Despite shortcomings, **eqn [5]** does focus attention on some of the key lifetime variables: the Al reservoir ( $C_0 - C_b$ ) and the Al consumption rate by oxidation ( $k$  and  $n$ ). It suggests that lifetime could be increased by decreasing the rate of consumption, or by increasing the Al reservoir either by increasing  $C_0$  or decreasing  $C_b$ . As discussed previously, the scale growth rate can be decreased by RE

**Figure 42** Total mass gain (specimen + spalled oxide) for ferritic Fe–17Al alloys (see **Table 2** examples) during 100 h cycles at 1250 °C in laboratory air. Specimens of alloys with only Y additions showed relatively short times to breakaway oxidation due to ‘broccoli’ formation.<sup>258</sup> Specimens with strong carbide-forming elements: Hf, Y + Hf or Y + Ti, prevent this form of attack associated with accelerated oxidation of grain boundary carbides. The co-doped alloy specimens had a much longer time to breakaway oxidation. Data from Pint.<sup>12</sup>

optimization. However, in commercial alloys, the possibility of achieving narrow composition targets may be an unrealistic goal. In terms of increasing  $C_0$ , alloy mechanical properties and the phase equilibria limit the amount of Al that can be added without significant negative consequences to other properties. **Figure 41** shows the relatively low lifetimes for some commercial alloys, Ohmalloy 30 and 40 and SUH21, all with lower Al contents (**Tables 1 and 2**). However, these alloys are easier to fabricate, process and join than alloys with higher Al content such as ODS alloys and Aluchrom YHf. Also, FeCrAl alloys become very brittle above 12 at.% Al.<sup>61</sup> Decreasing  $C_b$  is virtually impossible for FeCrAl alloys because  $C_b$  is already close to zero. For ferritic Fe(Al) alloys with higher Al contents (up to 19%), attempts to lower  $C_b$  from ~10% for binary alloys have been unsuccessful.<sup>12</sup> Additions of ‘third elements’ Mn and Cr were explored with little success.<sup>12,233</sup> Manganese appears to become quickly incorporated into the scale near the end of life and Cr additions appear to increase the CTE resulting in increased spallation. A general strategy of lowering the CTE, possibly with refractory metal additions, may be possible but has not been successful for Fe-based alloys to date.<sup>233</sup> A low CTE Ni-based bond coating has been developed.<sup>259</sup>

### 1.24.6 Effect of Environment

The previous sections discussed the oxidation behavior of alumina-forming alloys in  $O_2$  or air with low levels of water vapor in the ambient laboratory environment. In practice, high temperature applications tend to involve more complex environments. However, because of the inherent chemical inertness (i.e., thermodynamic stability) of  $\alpha$ - $Al_2O_3$ , alumina-forming alloys tend to have an advantage over conventional chromia-forming alloys under these conditions.

#### 1.24.6.1 Water Vapor

In actual applications, particularly those involving combustion, water vapor is commonly found in the environment. While Kofstad called the effect of water vapor on oxidation a ‘forgotten’ problem in 1991,<sup>260</sup> it has become a significant topic for research in the past decade because of increases in temperature application and the desire to use new materials. Also, combustion of hydrogen or synthetic natural gas from coal would increase the water content in the combustion product from 10 to 15% for natural gas or jet fuel to 60% for hydrogen, making water vapor more of a

concern.<sup>261</sup> As shown by Opila,<sup>262</sup> chromia and silica scales readily form oxy-hydroxides in the presence of H<sub>2</sub>O and O<sub>2</sub> resulting in accelerated oxidation attack for chromia-forming alloys and silica-based ceramics.<sup>263,264</sup> For typical stainless steels at 650–800 °C, the Cr consumption becomes linear due to the evaporation.<sup>265</sup>

As  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> is more stable than Cr<sub>2</sub>O<sub>3</sub> or SiO<sub>2</sub>, the reaction with water vapor is minimal until higher temperatures >1300 °C.<sup>262</sup> The effect of Al additions on resistance to water vapor is quite dramatic. Kvernes *et al.*<sup>266</sup> showed that small Al additions to Fe–Cr alloys were very effective in improving the oxidation resistance. Likewise, Pint *et al.*,<sup>267</sup> showed that additions of Al to austenitic Fe–15Cr–15Ni were very effective in reducing the detrimental role of water vapor. However, that study also showed that the addition of Al caused the formation of ferritic phases in the steel that decreased the 750 °C creep life by ~2 orders of magnitude, making the resulting alloy unacceptable for many applications. Recently, Brady and coworkers<sup>67–69</sup> showed that careful composition control and minor element additions could produce an Fe-based alumina-forming austenitic steel with very good creep strength and resistance to water vapor environments. This alloy is a potential solution to the problem of degradation of heat exchangers or recuperators for small turbines.<sup>268</sup> Compact, high-efficiency primary surface recuperators for these turbines require <100  $\mu$ m thick foil with good creep and oxidation resistance.

The excellent resistance of alumina scales to water vapor has led to extensive work on alumina-forming coatings on Fe-based alloys for combustion and steam environments. Thin coatings can improve oxidation resistance to steam for Fe–9Cr alloys for >40 kh at 650 °C.<sup>269</sup> Ferritic Fe(Al,Cr) weld overlaid coatings have shown promising results for boiler applications at <600 °C.<sup>270</sup> Coatings are further addressed in a separate chapter.

Several studies have examined the effect of water vapor on Ni-based alloys.<sup>261,271–274</sup> The general conclusions focused on three effects of water vapor on alumina-scales are: (1) Water vapor increases the spallation rate of alumina scales, particularly for marginally adherent scales. Smialek<sup>275</sup> suggested that this could be due to water vapor increasing the crack growth rate at the metal-scale interface. Figure 43 shows the specimen mass gain for NiAl + Hf and NiCrAlYHf specimens in dry O<sub>2</sub> and air with 10–90 vol.% H<sub>2</sub>O. For NiCrAlYHf, the drop in mass gain suggests scale spallation which increases with

**Figure 43** Specimen mass gain for cast Ni–20Cr–10Al + Y,Hf and Ni–48Al–0.05Hf specimens (see Table 2) exposed to 1 h cycles at 1100 °C in dry O<sub>2</sub> or air with various vol% of H<sub>2</sub>O from 10 to 90%. The addition of water vapor caused a minor increase in the mass gain for Hf-doped NiAl and a slight increase in spallation (mass losses) after 800 cycles for NiCrAlYHf. Data from Pint<sup>12</sup> and Pint *et al.*<sup>261</sup>

H<sub>2</sub>O content. (2) A small increase in the oxidation rate. The mass gain of NiAl + Hf increases with H<sub>2</sub>O content suggesting a slight increase in the rate constant (Figure 43). This was also noted for Fe-based alloys.<sup>276</sup> (3) A decrease in selective oxidation. On low Al alloys, more Ni-rich spinel oxide was formed with the addition of water vapor. This is a particular concern for uncoated superalloys and  $\gamma$ – $\gamma'$  NiPtAl coatings with low Al content.<sup>82,261</sup> An explanation for this decrease based on H injection into the substrate may apply to both alumina- and chromia-forming alloys.<sup>277</sup> Nevertheless, for adherent alumina-forming alloys with adequate Al, these effects are relatively minor as shown by the data in Figure 43 where even 90% water vapor caused a minor effect at 1100 °C.

#### 1.24.6.2 Sulfur and Hot Corrosion

A wide range of environments contain sulfur, sulfur-containing compounds (i.e., hot corrosion) or, more commonly, mixtures of S and O such as in coal-fired combustion (SO<sub>x</sub>) or gasification (H<sub>2</sub>S, low  $p$ O<sub>2</sub>), which was extensively investigated in the 1980s. For purely sulfidizing and hot corrosion (salt) environments, alumina-forming alloys are only marginally effective since Al does not really form a selective, protective sulfide layer and can be fluxed away by sodium–sulfate salts. As a result, the sulfidation

reaction of the base metal is a key issue. Ni-based alumina-forming alloys will be catastrophically affected by the formation of a liquid Ni-S reaction product above 700 °C.<sup>278,279</sup> Cobalt-based alloys are thought to be more resistant to sulfidation. Therefore, CoCrAl alloys and coatings have been developed for their sulfidation and hot corrosion resistance.<sup>280,281</sup> For Fe-based alumina-formers, some improvement is associated with the addition of Al compared to FeCr alloys but the sulfidation rates are still relatively high.<sup>282</sup> For example, a 150 µm thick scale was formed in 7 h at 800 °C with a  $pS_2 = 0.1$  Pa.

For oxidizing-sulfidizing environments, the performance of Fe-based alumina-forming alloys in petroleum environments has been investigated for more than 40 years.<sup>283</sup> Since then a great deal of work has been conducted on Fe(Al) and FeCrAl alloys in low oxygen, high sulfur pressure environments.<sup>50,284–288</sup> Under these conditions, binary (low Cr) Fe-Al alloys are generally superior to FeCrAl alloys because of the possible sulfidation reaction with Cr. However, ~19%Al is needed in Fe(Al) for this sulfidation resistance.<sup>286</sup> A similar level of Al was needed at the surface of Fe-Al coatings for a protective scale to form.<sup>289</sup> However, these experiments were typically performed at ~800 °C. At lower temperatures, 400–600 °C, where reaction rates are lower and it is more difficult to form alumina, the presence of Cr may be beneficial and work better than Fe-Al materials. This has been observed for Fe<sub>3</sub>Al and FeCrAl porous metal filters used in sulfidizing environments.<sup>12</sup>

Several studies suggest that additions of Y and Zr are beneficial to corrosion resistance in sulfur-containing environments at 600–800 °C.<sup>284,285</sup> In some mixed O-S environments it is possible to form an alumina scale that could be protective. Another common strategy has been to preoxidize the alloy in an oxidizing environment prior to exposure to S-bearing gases, particularly for FeCrAl.<sup>290–292</sup> If metastable, cubic alumina phases form during preoxidation, the volume reduction and associated scale cracking during the transformation to  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> will likely be detrimental to performance.<sup>292</sup> Thus, the preoxidation step must be controlled to assure an  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> preoxidation scale. While preoxidation has been successful in laboratory tests, in practice it has been less effective. In some applications, the problem is probably due to the damage of the preoxidation scale during subsequent handling and joining.

Even when the alumina scale is adherent and dense, it has been shown that S will penetrate

alumina scales and S was found segregated to  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> grain boundaries using STEM after exposure to a H<sub>2</sub>-H<sub>2</sub>O-H<sub>2</sub>S environment.<sup>293</sup> Cracks in the scale are another possible route for S penetration.

Hot corrosion, generally associated with Na<sub>2</sub>SO<sub>4</sub> salts, can be decreased by the formation of an adherent alumina scale. For example, on  $\gamma$ - $\gamma'$  NiPtAl compositions, preoxidation was very effective in reducing hot corrosion attack.<sup>91</sup> Therefore, RE additions and Pt may be somewhat beneficial in hot corrosion.<sup>294</sup> However, because of the fundamental fluxing reaction controlling hot corrosion,<sup>295</sup> Cr is much more effective than Al or Pt in reducing hot corrosion attack.<sup>296</sup>

#### 1.24.6.3 Carbon

For environments with high C activity where internal carburization and metal dusting occur,<sup>297</sup> alumina-forming alloys appear to be oxidation resistant. Compared to chromia-forming stainless steels, where the Cr<sub>2</sub>O<sub>3</sub> scale appears to allow the ingress of C, alumina scales appear to prevent C penetration.<sup>298,299</sup> The addition of Al or alumina-forming coatings appears to solve many C-related oxidation problems.

Again, the issue of alloy strength and joining is a critical one for alloy selections in many relevant applications. Alumina-forming alloys may not have the necessary strength or can be difficult to fabricate or join for commercial applications where high carbon activities are a concern. Recently, cast NiCrAlY alloy tubes have been developed for steam reforming applications.<sup>29</sup> The authors reported no major drop in creep strength or weldability. In addition, the relatively inert alumina scale had an additional benefit of reducing surface coke formation.

#### 1.24.6.4 Nitrogen

Nitrogen containing environments appear to be one condition that can cause problems for alumina-forming alloys. It appears that N can permeate through alumina scales and internally nitride alumina-forming alloys.<sup>93,299</sup> Most likely, the N permeation is not diffusion through dense alumina but penetration in the cracks in the scale. However, diffusion along  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> grain boundaries, like S, cannot be ruled out. For Fe-based alumina-forming alloys, internal nitridation has been observed in atmospheres with predominantly N and low  $pO_2$ .<sup>299–301</sup> Both Al and Ti (when present) are internally nitride. Internal nitridation of Al is observed at higher  $pO_2$  levels when the Al content is decreased

during extended exposure. As mentioned previously, internal nitridation has been observed for undoped Fe(Al) alloys in air but not for undoped FeCrAl.<sup>93</sup>

For Ni-based alloys, Han and Young<sup>302</sup> found that internal oxidation and nitridation of Ni–Al–Cr alloys was a result of heavy spallation which depleted the alloy in Al and caused a phase transformation. The internal nitridation of Ni-based superalloys is commonly observed<sup>303</sup> and was briefly reviewed by Krupp and Christ.<sup>304</sup> Their study of model NiCrAlTi alloys concluded that higher Cr contents increased the N solubility and diffusivity in NiCrAlTi alloys.

Bennett and coworkers<sup>305</sup> also found internal nitridation of FeCrAl by ‘crevice corrosion.’ In this case, it was proposed that in crevices in components, O could be locally depleted in the gas due to reaction with the surrounding metal and stagnant flow. The resulting high N and low O environment could cause internal attack.

### 1.24.7 Summary

Alumina-forming alloys are the most oxidation resistant alloys due to their low oxidation rates and thermodynamically stable scale. However, because of the negative effects of Al on alloy mechanical properties, fabrication, and joining, alumina-forming alloys are not widely used except when needed in very high temperature applications or in particular environments such as those with water vapor (or steam) and high C activities. As application temperatures increase in search of higher generation and production efficiencies, the use of alumina-forming alloys or coatings will inevitably increase.

### Acknowledgments

The author would like to thank his colleagues at ORNL, acknowledge the discussions with I. G. Wright, appreciate the comments on the manuscript from M. P. Brady and P. F. Tortorelli, and gratefully acknowledge the assistance provided by the dedicated technical staff, L. D. Chitwood, G. W. Garner, J. L. Moser, H. F. Longmire and L. R. Walker for the experimental work. The manuscript preparation was sponsored by the U.S. Department of Energy, Fossil Energy Advanced Research Materials Program and work at the SHaRE User Facility by the Division of Scientific User Facilities, under contract DE-AC05-00OR22725 with UT-Battelle, LLC.

***C<sub>Al</sub>*** Concentration of aluminum ( $\text{m}^{-3}$ )  
***C<sub>b</sub>*** Bulk concentration (at.%)  
***D*** Interdiffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ )  
***D<sub>Al</sub>*** Interdiffusion coefficient for aluminum ( $\text{m}^2 \text{s}^{-1}$ )

***E<sub>m</sub>*** Young's modulus of the alloy or metallic coating (Pa or GPa)  
***E<sub>ox</sub>*** Young's modulus of the oxide (Pa or GPa)  
***f<sub>B</sub>*** Bulk fractional concentration of solute  
***f<sub>i</sub>*** Fractional concentration of solute at oxide-coating interface  
***f(x)*** Fractional concentration at position *x*  
***h*** thickness of oxide layer (m)  
***h<sub>o</sub>*** Preexisting oxide thickness (m)

$J_{Al}$	Flux of aluminum ( $m^{-2} s^{-1}$ )
$k_n$	Oxidation rate constant ( $m^n s^{-1}$ )
$k_p$	Parabolic oxidation rate constant ( $m^2 s^{-1}$ )
$k'_p$	Mass gain parabolic rate constant ( $g^2 m^{-4} s^{-1}$ or $mg^2 cm^{-4} s^{-1}$ )
$M_o$	Atomic weight of oxygen (kg)
$M_{ox}$	Molecular weight of the oxide (kg)
$n$	Dimensionless number
$R$	Radius of decohesion zone (m)
$t$	Exposure time (s)
$T$	Temperature (K)
$T_{ox}$	Oxidation temperature (K)
$\Delta T$	Amplitude of temperature change (K)
$\Delta T_b$	Critical temperature change for oxide buckling (K)
$\Delta T_c$	Critical temperature change for oxide spallation (K)
$v$	Volume of oxide formed per aluminum atom ( $m^3$ )
$w$	Half the specimen or cell thickness (m)
$W^*$	Strain energy ( $J m^{-3}$ )
$W_{Al}$	Atomic weight of aluminum (kg)
$W_{Al_2O_3}$	Molecular weight of alumina (kg)
$x$	Spatial coordinate and distance from the oxide-metal interface (m)
$x_h$	Section loss (m)
$\alpha_m$	Linear thermal expansion coefficient of alloy or coating ( $K^{-1}$ )
$\alpha_{ox}$	Linear thermal expansion coefficient of oxide ( $K^{-1}$ )
$\varepsilon$	Strain
$\phi$	Pilling-Bedworth ratio
$\gamma_F$	Effective fracture energy ( $J m^{-2}$ )
$\nu$	Poisson's ratio
$\rho_{Al_2O_3}$	Density of alumina ( $kg m^{-3}$ )
$\rho_m$	Density of the alloy ( $kg m^{-3}$ )
$\rho_{ox}$	Density of the oxide ( $kg m^{-3}$ )
$\sigma_{ox}$	In-plane oxide stress (Pa or MPa)

### 1.27.1 The Need for Coatings

High temperature superalloys, usually based on iron-, cobalt-, or nickel-rich compositions,<sup>1</sup> are optimized for mechanical properties, such as creep and fatigue resistance, since they are used for highly-stressed components. In all cases, however, these alloys will be exposed to oxidizing or hot-corrosion environments during service and will undergo some form of degradation process resulting from this interaction. The composition optimization required to achieve good mechanical properties, however, often conflicts with the requirements for

oxidation/hot-corrosion protection. As a result, the intrinsic protection capability of many superalloys is adequate only for short-term exposures and coatings are required to permit extended operation under service conditions. This point will be demonstrated in the later text for the particular case of Ni-based superalloys under oxidizing conditions.

High-strength nickel-based alloys are used extensively for components in gas turbines; an excellent account of their development and properties is provided by Reed.<sup>1</sup> Single crystal alloys, for example, CMSX4, are used for high-pressure blades in aeroengines and in small ( $\sim 10$  MW) land-based turbines, but, in larger machines, polycrystalline alloys (e.g., IN738LC) are used. Some compositions of nickel-based alloys are given in Table 1. These are given in 'weight percentage' as is customary, but, in assessing the ability to form and maintain a protective alumina layer at high temperatures, it is the atomic percentage of available aluminum which is a key factor. For alloys having high nickel, chromium, and cobalt contents, the atomic concentration of aluminum is roughly twice the weight percentage value. In more complex alloys containing appreciable amounts of heavy elements such as tungsten, rhenium, or ruthenium, this factor is nearer 2.5. Thus, even though in most of the alloys (shown in Table 1) the aluminum concentration is  $\sim 5.6$  wt%, its atomic concentration increases from  $\sim 11$  at.% in simpler alloys such as RR2000 to  $\sim 13$  at.% in PWA1497. Much of this aluminum is associated with the strengthening  $\gamma'$  phase in these alloys.

The importance of both aluminum and chromium concentrations to the ability of a Ni-based alloy to form a protective alumina layer is summarized in Figure 1. This diagram is similar to that given by Evans and Taylor,<sup>2</sup> but has been modified to reflect the low-Cr compositions of the more recent alloys shown in Table 1 and to include  $\gamma/\gamma'$  coatings. For convenience in comparing between alloys, concentrations in weight percentage are used. The experimentally based lines shown in Figure 1 derive from the work of Giggins and Pettit<sup>3</sup> on NiCrAl alloys at temperatures within the range 1000–1200°C. They show that in simple Ni–Al binary alloys, at least 6 wt % aluminum is required to form an alumina layer at these temperatures. This critical value decreases with increasing alloy chromium content to  $\sim 3$  wt% aluminum at chromium contents  $\geq 10$  wt%. At low aluminum and chromium contents, that is, below the downward sloping line to the left-hand side of Figure 1, the principal surface oxide is expected to

**Table 1** Compositions (wt%) of some representative nickel-based superalloys

Alloy	Ni	Co	W	Cr	Al	Ta	Re	Hf	Ru	Ti	Mo	Nb

**Figure 1** A schematic map derived from Evans and Taylor,<sup>2</sup> based on experimental data<sup>3</sup> showing the type of oxide formed in the NiCrAl system over the temperature range 1000–1200 °C. Superimposed are the composition ranges of typical superalloys and coatings.

be NiO (in NiCrAl alloys), with internal oxidation of aluminum and chromium. To the right-hand side of **Figure 1**, corresponding to alloys of high chromium and low aluminum content, chromia will be the expected surface oxide and aluminum will oxidize internally.

Also shown schematically, as the cross-hatched ellipse in **Figure 1**, is the approximate range of aluminum and chromium contents often used in Ni-based superalloys. It is immediately apparent that they tend to lie on or near the bounding lines for protective alumina formation. In some cases, alumina formation can be expected but not in others. As a group, these Ni-based superalloys can be considered to be borderline alumina formers and nonprotective oxidation has been reported in this temperature range for IN738LC<sup>4,5</sup> and CMSX10.<sup>6</sup> The situation

is exacerbated with recent generations of alloys in which chromium levels have been decreased to ~2–2.5 wt% (**Table 1**), making it less favorable for a protective layer of alumina to form (see **Figure 1**). In addition, elements such as rhenium and ruthenium have been introduced, which have volatile oxides that can be released at high temperatures, at least in the absence of a protective surface oxide layer.

Another important consideration when assessing the oxidation resistance of an alloy is its ability to reform a protective alumina layer should that which formed initially spall or crack. This is an arduous requirement for borderline alloys, since the formation and growth of the original alumina layer is a process of selective oxidation and necessarily depletes the alloy of aluminum. Thus, even though an alumina layer may have formed initially on the superalloy, residual aluminum concentrations are unlikely to be able to maintain protective conditions when repeated spallation events occur.

It is for this combination of reasons that Ni-based superalloys operating at elevated temperatures, say  $\geq 1000$  °C, are coated with Al-rich layers. The composition ranges of two important classes of such coatings, overlays and diffusion coatings, are shown in **Figure 1**. These will be discussed shortly but, clearly, both types are designed to lie within the alumina-forming region in the diagram. It is the combination of high-strength superalloy and oxidation-resistant coating that permits component operation for extended periods at high temperatures.

## 1.27.2 Underlying Requirements of Coatings

### 1.27.2.1 The Protective Oxide Layer

High temperature coatings rely, for protection, on the formation of a dense and adherent surface oxide layer that is chemically stable, thickens slowly with time at temperature, and has good adherence to the coating.

These are, of course, the same requirements as are needed in the design of oxidation-resistant alloys in general, as discussed elsewhere in this book, and, as in that case, the choice is limited to chromia ( $\text{Cr}_2\text{O}_3$ ), silica ( $\text{SiO}_2$ ), and alumina ( $\alpha\text{-Al}_2\text{O}_3$ ).

Chromia layers are particularly useful in conferring protection against Type-II hot corrosion<sup>7</sup> and intermediate-temperature oxidation, say 600–800 °C, but can be converted to  $\text{CrO}_3$  at higher temperatures. The rate of formation of this gaseous oxide can be significant in both dry and moist air at temperatures  $\geq 950^\circ\text{C}$  and chromia-forming coatings have limited usage at high temperatures in such environments. Silica layers are capable of providing protection to very high temperatures, for example, *via* ceramic layers on carbon-based materials, to  $\sim 1800^\circ\text{C}$ .<sup>8</sup> They also suffer, however, from concerns with chemical stability in moist environments. Alumina layers do not suffer from such concerns and are the favored means of protection under Type-I hot-corrosion and high temperature oxidation conditions. The majority of coatings are now designed to form a continuous alumina layer under these conditions and to have sufficient aluminum content to provide a healing capability in the event of cracking or spallation of this layer. The majority of this chapter will place emphasis on the behavior of such alumina-forming coatings designed for use under high temperature oxidizing conditions, but interesting exceptions with commercial relevance are also included.

### 1.27.2.2 Coating Composition and Solute Supply

The initial priority of oxidation-resistant coatings is to form a protective layer that can be achieved simply by incorporating sufficient amount of the relevant element into the coating composition. However, this approach can impair physical and mechanical properties, for example, by decreasing melting temperatures or coating fracture toughness and ductility, and a balance must always be sought. The composition ranges of three types of alumina-forming coatings are shown in **Figure 1**, from which it is clear that all lie in the appropriate composition range for protective oxide formation. Detailed discussion of the coating types is provided later, but it is clear that aluminum concentrations of  $\sim 10\text{ wt}\%$  are typical for both the MCrAlY overlays and  $\gamma/\gamma'$  diffusion coatings. These compare with the minimum requirements for alumina formation (solid lines) of  $\sim 3$  and  $6\text{ wt}\%$  aluminum, respectively. The  $\beta$ -forming class of diffusion coating has substantially larger amounts of aluminum at  $\sim 25\text{ wt}\%$ .

It must be borne in mind, though, that the formation of the protective layer is a process of selective oxidation in which the solute atom is preferentially removed from the coating, oxidized, and incorporated into the oxide layer. This removal necessarily depletes the coating of the solute and will generate a concentration profile as shown schematically in **Figure 2** for the case of aluminum removal from, nominally, a NiCrAlY overlay coating. This is assumed to have had an initial aluminum concentration of  $10\text{ wt}\%$  and can be compared with the uncoated alloy having an initial concentration of  $5.6\text{ wt}\%$ .

The second requirement of a protective coating is that the residual solute concentration after initial formation of the surface layer is still sufficient to reform a protective layer in the event of cracking or spalling of this first-formed layer. As shown in **Figure 2**, the coating has sufficient aluminum, and hence even after alumina formation, there is still sufficient solute at the oxide–metal interface to reform this layer. By contrast, because the superalloy had barely sufficient aluminum to form the alumina layer initially, the interfacial concentration falls below the critical value after formation of the protective layer. Subsequent spallation of this layer would then mean that rapid oxidation of the alloy would take place until the local concentration had reached the critical value for reforming the alumina layer. The quantity of metal consumed is shown by the hatched area in **Figure 2** as  $\sim 7\text{ }\mu\text{m}$  but it will be much larger if spallation occurs later in life when more pronounced depletion has occurred. Typically, the thickness of this at-risk zone will increase parabolically with exposure time up to the first spallation event.

The shapes of the depletion profiles shown in **Figure 2** are determined by the need to maintain a mass balance at the oxide–metal interface, such that the flux of aluminum leaving the metal is equal to that required to produce the observed thickening rate of the oxide.<sup>9</sup> Considering the ideal case that the oxide thickness,  $b$ , increases parabolically with time,  $t$ , and forms at the start of the exposure period, the rate constant,  $k_p$ , is then defined as

$$k_p = b^2/t \quad [1]$$

This means that the flux of aluminum atoms,  $\mathcal{J}_{\text{Al}}$ , arriving at the oxide–metal interface is

$$\mathcal{J}_{\text{Al}} = -D_{\text{Al}} \left( \frac{\partial C_{\text{Al}}}{\partial x} \right)_{x=0} = \frac{1}{V} \left( \frac{d\xi}{dt} \right) = \frac{1}{2} k_p^{0.5} t^{-0.5} \quad [2]$$

where it is assumed, reasonably for protective conditions, that the recession of the oxide–metal interface is much smaller than the diffusion distances within

**Figure 2** Selective oxidation of aluminum from a NiCrAlY coating and superalloy produces depletion profiles in that element. They result in interfacial aluminum concentrations insufficient to reform the alumina layer on the superalloy without the prior consumption of some of the underlying metal. The critical interfacial concentration for reforming an alumina layer is taken as 3 wt%, that is, of similar magnitude to those shown as solid lines in Figure 1.

the coating. In eqn. [2],  $D_{Al}$  is the interdiffusion coefficient for aluminum within the coating,  $C_{Al}$  is the aluminum concentration (number/unit volume),  $x$  is the spatial coordinate measured from the oxide-metal interface, and  $V$  is the volume of oxide formed per aluminum atom. The depletion profile within the metal can then be obtained from solution of Fick's second law

$$\frac{\partial C_{Al}}{\partial t} = D_{Al} \frac{\partial^2 C_{Al}}{\partial x^2} \quad [3]$$

using eqn. [2] as a boundary condition, that is, the flux of aluminum at the oxide-metal interface varies as  $\bar{t}^{-1/2}$ . At relatively short exposure times, the depletion distance will be small compared with the thickness of the coating so that the latter can then be considered as semiinfinite. Under these conditions, the depletion profile is obtained as<sup>10</sup>

$$\frac{f(x) - f_i}{f_b - f_i} = \operatorname{erf} \left( \frac{x}{2(D_{Al}t)^{0.5}} \right) \quad [4]$$

where the  $f$ s are consistent concentration parameters, for example, weight (mass) fractions,  $f(x)$  is the value at distance  $x$ ,  $f_i$  is the value in the metal at the oxide-metal interface,  $f_b$  is the bulk value, and  $\operatorname{erf}$  is the error

function. The interfacial concentration,  $f_i$ , is constant provided that parabolic oxidation and semiinfinite conditions apply, but its value is directly related to the rate constant  $k_p$  and can be determined from the need to conserve the aluminum flux at the oxide-metal interface. For simplicity, taking  $f$  as a weight fraction, the interfacial concentration during the growth of alumina is given as<sup>11</sup>

$$f_i = f_b - \left[ \left( \frac{\pi k_p}{D_{Al}} \right)^{1/2} \left( \frac{\rho_{Al_2O_3} W_{Al}}{\rho_m W_{Al_2O_3}} \right) \right] \quad [5]$$

Here,  $\rho$  is density,  $W$  is molecular or atomic weight, the suffix 'm' is the coating, and  $Al_2O_3$  the oxide.

The concentration in the coating at its interface with the oxide will be maintained provided that there is sufficient aluminum reservoir and thickness of the coating to approximate to semiinfinite conditions. Protection should, thus, be provided by these generic coatings until end-of-life effects, initiated often by aluminum-reservoir depletion, intervene. At this stage, the interfacial concentration will begin to decrease and a level will eventually be reached where the protective alumina layer cannot be maintained. These issues will be discussed in detail in the following sections.

## 1.27.3 Examples of Main Coating Types

### 1.27.3.1 Overlay Coatings

#### 1.27.3.1.1 MCrAlY coatings

Overlay coatings consist of a discrete coating layer deposited onto the surface of the component, with little interdiffusion and chemical reaction with the alloy substrate. These overlay coatings are often metallic alloys, 150–300  $\mu\text{m}$  thick, based on MCrAlY compositions where M is Ni, Co, sometimes Fe, or a combination of these. Early development of these overlay coatings centered on cobalt-based materials containing 20–40 wt% Cr, 12–20 wt% Al, and 0.5 wt% Y.<sup>12</sup> On the basis of hot corrosion and mechanical property tests, an optimal composition of Co<sub>25</sub>Cr<sub>14</sub>Al<sub>0.5</sub>Y (wt%) was selected. This initial composition is similar to those of the more recent Co-based coatings, ATD 2B and ATD 5B, given in Table 2. Later trends, however, have been to replace some or all of the cobalt content with nickel in order to improve toughness and to limit interdiffusion effects when protecting high temperature Ni-based superalloys. There has also been a tendency to decrease aluminum content, again to improve coating toughness. A few examples of the composition of current MCrAlY overlay coatings are given in Table 2.

It is sometimes the case, as can be inferred from Table 2, that overlay coatings of the same or similar compositions have different designations, for example, LCO22 and CN122. This reflects the different possible deposition methods in commercial use. These include air plasma spraying (APS), argon-shrouded plasma spraying (ASPS), low-pressure plasma spraying (LPPS), high-velocity oxy-fuel (HVOF) spraying, electrodeposition, and physical vapor deposition (PVD) processes such as sputtering and electron beam (EB) PVD. Some of these methods

relate to the coatings shown in the table. Details of these techniques and the historical development of protective coatings can be found elsewhere.<sup>13–18</sup>

Even though the details of the coating techniques will be covered elsewhere in this book, it is important to note that different application methods will produce different coating structures as can be appreciated from Figure 3. In both of the plasma sprayed coatings, (a) and (b), the sequential spray runs are evident in the lateral dark stringers of oxide formed around individual alloy particles during the deposition process. These stringers can be continuous in the APS coating in which extensive oxidation in the air environment can result. Some oxide formation is inevitable also under LPPS, as can be appreciated from Figure 3(b), but in this case, continuous stringers are not usually formed (e.g., see Figure 4). These differences affect the longevity of the coatings, even for a given nominal composition, as will be discussed later with reference to aluminum reservoir issues. The EB-PVD coating, by contrast, forms as vertical columns with negligible oxidation. These vertical features can be seen on closer inspection in Figure 3(c), and their presence provides sites of potential mechanical weakness, which can be removed by postprocessing, for example, peening, to improve lateral bonding.

The MCrAlY coatings (shown in Table 2) have a nominal  $\beta/\gamma$  structure, where  $\beta$  can be NiAl or CoAl and  $\gamma$  is face-centered cubic Ni- or Co-rich solid solution. In practice, however, the actual microstructure will depend on cooling rate and temperature as well as on the detailed composition. Ni-rich phases, for example, can undergo the following four-phase reaction at  $\sim 980^\circ\text{C}$ <sup>19</sup>:

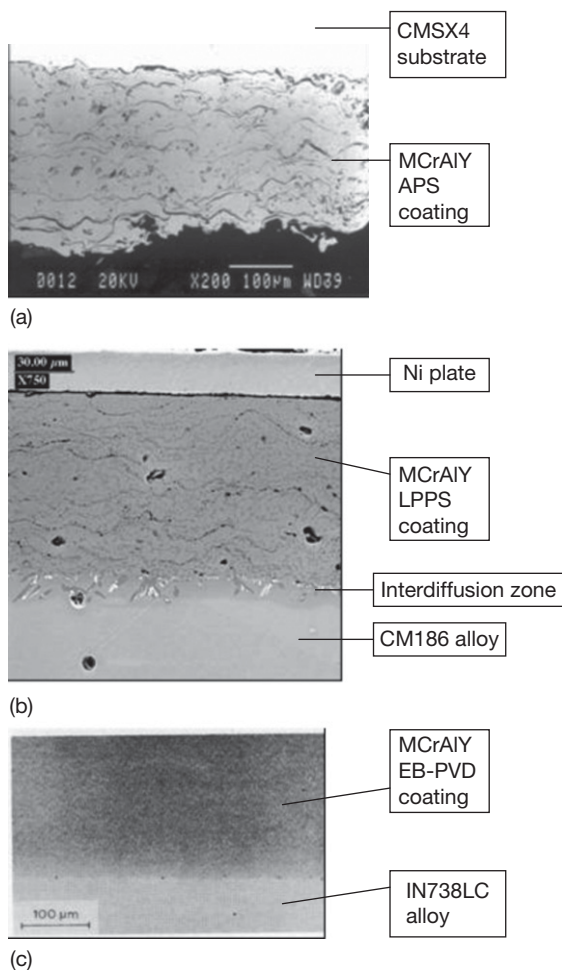

where  $\gamma'$  is the Ni<sub>3</sub>Al phase and  $\alpha$  is the  $\alpha$ -Cr solid solution. It can be appreciated that a given coating

**Table 2** Compositions (wt%) of some MCrAlY overlay coatings

**Figure 3** Examples of the structure of MCrAlY coatings deposited by (a) APS,<sup>2</sup> (b) LPPS,<sup>2</sup> and (c) EB-PVD<sup>13</sup> techniques.

composition can have a  $\beta/\gamma$  microstructure at higher temperatures, but at lower temperatures – often corresponding to service conditions – can be  $\gamma'/\alpha$ . In reality, particularly if fairly rapid temperature changes take place, the microstructure may be non-equilibrium and contain a mixture of the various phases.<sup>20</sup> An example of a typical duplex microstructure is provided in **Figure 4**. Further complications may arise near the interface with the substrate alloy if  $\gamma'$ -stabilizing elements such as tantalum, titanium, and niobium have diffused into the coating; the  $\gamma'$  phase can then exist to temperatures above 980 °C at this location.

Reaction [6] is also accompanied by linear contraction strains of  $\sim 0.7\%$  and there has been concern that this could prejudice the integrity of the coating. There is no particular evidence for any deleterious

**Figure 4** The duplex microstructure of a LPPS CoNiCrAlY overlay coating. Courtesy of Dr. M.P. Taylor.

effect, however, possibly because the strains arise at temperatures where the coating is ductile and stress relaxation rates are high.<sup>21,22</sup> Nevertheless, the concern has been one of the historic factors influencing the incorporation of cobalt into many coating compositions in order to decrease the stability of the  $\gamma'$  phase. Even so,  $\gamma'$  phases have been reported<sup>20</sup> in Ni-based MCrAlY coatings containing 20 wt% Co.

Minor alloying additions, in addition to yttrium, have also been made to MCrAlY coatings either in attempts to improve alumina formation or adherence or to improve mechanical properties. Some examples include silicon<sup>23</sup> and hafnium<sup>24</sup> and also tantalum (**Table 2**), titanium,<sup>23</sup> molybdenum (**Table 2**), niobium, rhenium, and zirconium. These are often used in combinations, but detailed compositions of current coatings tend to be proprietary. MCrAlY coatings have also been modified by means of surface enrichment with silicon<sup>25</sup> and aluminum (e.g., GE coatings 29+ and 33+) and, in lower-density air plasma sprayed structures, by inward percolation of liquid  $\text{NiAl}_3$ .<sup>26</sup>

#### 1.27.3.1.2 Examples of other metallic coatings

Much effort has been made to deposit metallic coatings other than MCrAlYs in attempts to improve substrate properties<sup>15</sup>; some examples designed to confer oxidation resistance are given here.

Ti–Al alloys have considerable commercial potential because of their high specific creep strength, that is, the combination of good creep strength and low density. Their disadvantage lies in their poor oxidation resistance resulting from the competitive growth of alumina and rutile ( $\text{TiO}_2$ ). Both of these oxides are very stable, but the latter has a much higher growth rate than alumina and the combination makes it difficult to form and sustain protective conditions.

The situation can be improved by the application of surface coatings of increased aluminum to titanium ratios having greater propensity to form alumina. Interesting examples are the use of a sputtered Ti–51Al–13Cr (at.%) overlay<sup>27</sup> to improve oxidation performance of a near- $\alpha$  titanium alloy at 750 °C in air. A similar principle has been adopted<sup>28</sup> through the use of either graded or discrete sequential layers of Ti<sub>3</sub>Al, TiAl, and TiAl<sub>3</sub>, again on a near- $\alpha$  alloy. In an alternative approach,<sup>29</sup> it is recognized that at typical operating temperatures for Ti–Al (say 700–750 °C), it is not necessary to use an alumina layer for oxidation protection, since a chromia layer will provide the necessary improvements. As a consequence, it is possible to use Al-free chromia-forming coatings of high fracture toughness and ductility to confer oxidation protection.<sup>29</sup>

Overlay coatings may also allow the potential of other reactive alloys with attractive mechanical properties to be realized. Important examples are those alloys based on niobium, which have good creep properties at high temperature but poor oxidation resistance. Alumina-forming FeCrAlY and silica-forming SiCrAlY overlays, deposited by APS, can produce oxidation protection to molybdenum for significant periods, 300 and 2000 h, respectively, at 1200 °C.<sup>30</sup> An advanced coating architecture for the protection of a Nb–5Mo–15W alloy has been developed by Narita and coworkers,<sup>31</sup> in which the outer Al-rich reservoir within the coating is protected from interdiffusion by underlying Re–Cr-rich layers.

### 1.27.3.1.3 Oxide overlay coatings

Directly depositing a surface coating of a protective oxide layer ought, in principle, to be an attractive option, since it bypasses the need for the metallic element to be present in significant quantities in the underlying alloy. This is particularly the case for aluminum and silicon, whose presence in large amounts can impair the mechanical properties of the alloy.

A low-cost method for the deposition of an oxide coating is through the use of sol-gels.<sup>15,32</sup> In this, the coating is formed by evaporation of a colloidal suspension of oxide or hydroxide particles and subsequent consolidation of the deposit to form a dense layer. A common feature, though, is the formation of cracks during the curing process, which necessitates the use of multilayers to confer reasonable oxidation protection. Even so, crack-like defects will exist within the layer thickness, which will lead to decreased coating ductility. A better approach is to produce the oxide layer from the vapor phase and this has had considerable success with

the formation of silica coatings. An early evaluation of silica coatings, produced from silane onto a 9Cr ferritic steel, has been made by Crouch and Dooley.<sup>33</sup> Later developments have used plasma-assisted vapor deposition (PAVD) resulting from the decomposition of tetraethoxysilane. Very dense, uncracked, and adherent amorphous silica coatings up to 10  $\mu$ m thick have been produced by this method on, for example, Incoloy 800H,<sup>34</sup> IN 738LC<sup>35</sup> and 20Cr25Ni, Nb-stabilized austenitic steel.<sup>36</sup> The improvements in oxidation resistance obtained from these coatings have been substantial, for example, decrease by a factor of 5 in mass gain for IN 738LC after 5000 h exposure in air at 900 °C.<sup>35</sup>

A striking demonstration of the improvement obtained on the 20Cr25Ni austenitic steel at 1300 °C is given in Figure 5.<sup>37</sup> In this figure, the top micrograph shows how the entire cross-section of the uncoated specimen has been oxidized after 1 h exposure at this temperature in a CO<sub>2</sub>-based gas. In contrast, the silica-coated specimen (lower micrograph) is largely still intact. This example is particularly interesting, since the 20Cr25Ni, Nb-stabilized alloy is used as thin-walled (0.38 mm) tubes to contain UO<sub>2</sub> fuel in the UK's Advanced Gas-Cooled Reactors (AGRs). The test time and temperature used relate to postulated fault scenarios with restricted coolant flow.

These substantial improvements in oxidation resistance arise because the silica coating acts as a barrier both to the inward diffusion of oxygen and to

**Figure 5** Optical micrographs of cross-sections of specimens of a 20Cr25Ni, Nb-stabilized alloy after oxidation for 1 h at 1300 °C in a CO<sub>2</sub>/1% CO gas.<sup>37</sup> (a) Complete oxidation of the uncoated alloy and (b) relatively intact silica-coated specimen. The magnification is the same in each case.

the outward diffusion of the alloy constituents. A disadvantage, though, is that the coating offers no self-healing capability in the event that through-thickness cracks or localized spallation occurs. In other words, there is no reservoir of silicon available to reform the silica layer. Cracks in the layer will allow oxygen ingress to the underlying alloy and the continuing formation of nonprotective oxides.<sup>32</sup> The situation is aggravated in the case of amorphous silica because of its low linear thermal expansion coefficient of  $0.5 \times 10^{-6} \text{ K}^{-1}$ . Because the coating layer is much thinner than the metal thickness, it is reasonable to assume that the planar dimensions of the coating will follow those of the underlying alloy during a temperature change,  $\Delta T = (T - T_{\text{ox}})$ , (where  $T$  is the new temperature and  $T_{\text{ox}}$  is the original oxidation temperature). The in-plane strain,  $\varepsilon$ , within the coating is then given as

$$\varepsilon = \Delta T(\alpha_{\text{metal}} - \alpha_{\text{silica}}) \quad [7]$$

where  $\alpha$  is the respective thermal expansion coefficient. A detailed discussion of such mechanical issues has been given elsewhere,<sup>38</sup> but it is instructive here to calculate the thermal expansion strain in the silica coating of **Figure 5(b)**. Assuming that the silica layer was deposited at  $800^\circ\text{C}$ ,  $\Delta T = 500^\circ\text{C}$  for the temperature rise to the test temperature of  $1300^\circ\text{C}$ . Taking also  $\alpha_{\text{metal}} = 17.5 \times 10^{-6} \text{ K}^{-1}$  then gives a tensile in-plane strain within the silica coating of 0.85%. Interestingly, this is much higher than the fracture strain values at  $500^\circ\text{C}$  of 0.27–0.45% found by Crouch and Dooley<sup>33</sup> for sol-gel-deposited silica. It can be surmised from **Figure 5(b)** that the silica layer formed by PAVD remains uncracked, however, even after the  $500^\circ\text{C}$  temperature rise, since there is continued oxidation protection. It implies that the PAVD structure either contains fewer crack-like defects and, hence, has higher intrinsic ductility than the sol-gel equivalent or that creep processes at the oxidation temperature relax stresses at crack tips and, again, increase ductility.

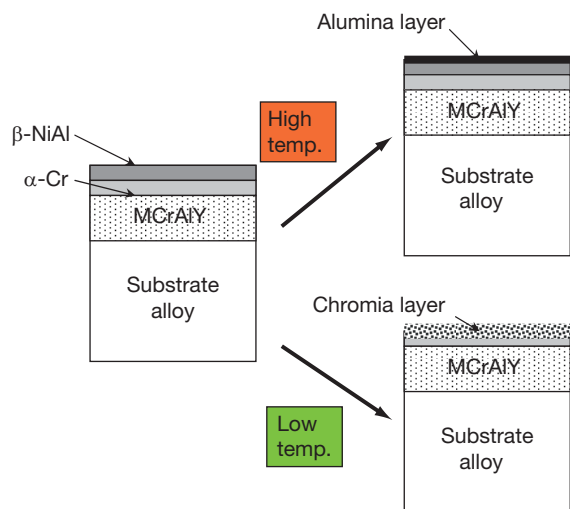

Eventual degradation of the amorphous silica layer is associated both with its transformation to the crystalline state ( $\alpha$ -cristobalite) and with reaction with cations from the alloy.<sup>34</sup>

### 1.27.3.2 SMART MCrAlY Overlay Coatings

The compositions of current MCrAlY coatings (**Table 2**) reflect a compromise between the need to provide protection against low-temperature Type-II hot corrosion and intermediate-temperature oxidation

and the need to protect against Type-I hot corrosion and high temperature oxidation. In the former case, high chromium levels and chromia protective layers are optimum whereas, in the latter case, high aluminum concentrations and protective alumina layers are more effective.<sup>7,39</sup> These coatings respond reasonably but not as well as coatings designed for specific local conditions of temperature and environment within, say, a large land-based gas turbine. Furthermore, the range of protection afforded by these coatings is limited and hampers moves to a more flexible operating regime in which various alternative fuels could be employed, for example, ranging from natural gas through kerosene, diesel oils to gaseous fuels made from coal, biomass, or waste.

*SMART* MCrAlY overlay coatings have been designed<sup>40,41</sup> to address this problem of flexibility and also the need to increase fuel efficiency by higher-temperature operation. Under these aggressive conditions, high temperature oxidation and both Type-I and Type-II hot corrosion may be experienced across a single component. The intention is for *SMART* coatings to respond to the local environment and to generate the optimum protective system to it, that is, either a chromia or an alumina layer. The coatings are chemically graded to provide surface layers enriched in aluminum and chromium, respectively, overlying a MCrAlY overlay coating. The structure is shown schematically in **Figure 6**. The

**Figure 6** Schematic diagram of the chemically-graded *SMART* coating structure showing the outer  $\beta$ -NiAl layer and the intermediate Cr-rich zone overlying the base MCrAlY coating. The right-hand figures show the expected response under different oxidation and hot-corrosion regimes.

outer layer consists of  $\beta$ -NiAl produced by aluminizing but before this treatment, the base MCrAlY coating had been pretreated to form an intermediate layer rich in chromium. Manufacturing details of this process are currently proprietary,<sup>41</sup> but it is the presence of this intermediate Cr-rich layer that distinguishes *SMART* coatings from over-aluminized variants, for example, GT33+, currently available.

Under high temperature oxidation or Type-I hot corrosion conditions, the outer layer of the *SMART* coating reacts to form an alumina layer and provide optimum protection. The Cr-rich intermediate layer acts as a diffusion barrier limiting interdiffusion and, particularly, the loss of aluminum from the outer layer into the base coating. Under Type-II hot corrosion conditions, say at 600–800 °C, the outer region of the coating forms an alumina layer sluggishly and is intended to be sacrificed to allow the corrosion front to encounter the intermediate Cr-rich layer at which a chromia protective layer will form. The rate of pitting attack, associated with Type-II corrosion, will then be substantially decreased at this stage.

Extensive testing of these coatings<sup>40,41</sup> under hot corrosion conditions has demonstrated that these concepts do work, as can be appreciated from the

montage of SEM micrographs of cross-sections of corroded specimens shown in Figure 7.<sup>40,41</sup> The test duration in all cases was 500 h in an air–400 vpm SO<sub>2</sub>/SO<sub>3</sub> environment and were recoated every 20 h in an 80% Na<sub>2</sub>SO<sub>4</sub>/20% K<sub>2</sub>SO<sub>4</sub> eutectic mix. Figure 7 shows a comparison of a *SMART* coating variant (SmC 155H) with a Pt-aluminized diffusion coating (RT22) and an over-aluminized CoNiCrAlY overlay coating in the as-produced condition and after testing at 700 and 800 °C. It can be seen that both commercial coatings have been severely corroded at both temperatures whereas the *SMART* variant is relatively unaffected at 800 °C and shows penetration only through the outer aluminized layer at the lower temperature.

### 1.27.3.3 Diffusion Coatings

#### 1.27.3.3.1 Basic types

Diffusion coatings are formed by direct interaction of the substrate alloy with elements, typically chromium, aluminum, and silicon, which are capable of forming protective oxide layers. Typically, coatings are produced through either immersion in a cementation-type pack or by vapor transfer of the

**Figure 7** Comparison of the corrosion morphology of a *SMART* coating variant with a RT22 (platinum-aluminide) coating and an over-aluminized MCrAlY coating.<sup>41</sup> See text for further details.

active species to the component remote from the pack at temperatures where concurrent diffusion in the alloy develops the coating layer. Details can be found elsewhere.<sup>13–18</sup> Unlike overlays, diffusion coatings produced by these methods have limited flexibility to vary composition, although it is possible to codeposit more than one reactive species, for example, Al/Cr,<sup>42</sup> Al/Si,<sup>43</sup> and Cr/Si<sup>44</sup> and to use predeposited layers, for example, platinum, to vary coating structure.<sup>45</sup> More flexibility with regard to coating composition can be achieved through the use of a slurry of reactive species, which can be painted or sprayed onto a work piece and subsequently diffusion annealed. By repetition of this process, multilayered coatings can be produced.<sup>46</sup> Important examples include Cr–Si- and Al–Si-rich compositions, for example, Sermaloy J and Sermetal 1515.

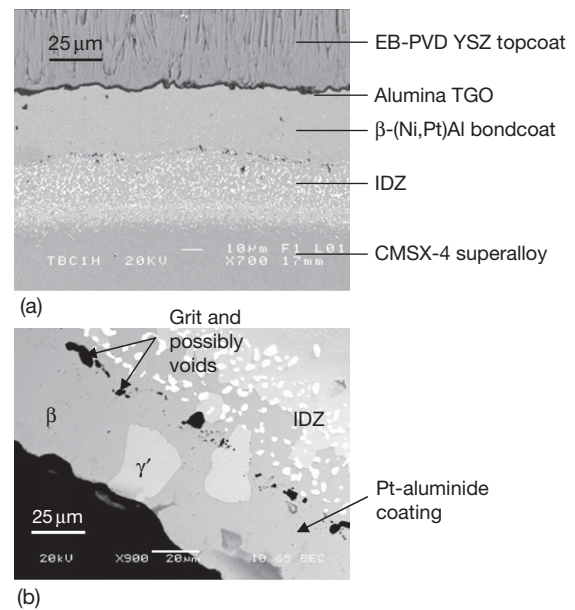

Chromizing can be used with both iron- and nickel-based alloys to provide protection at moderate temperatures (700 °C) against Type-II hot corrosion and intermediate-temperature oxidation. The concentration of chromium in the alloy surface can be raised to 40–80 wt% and this is sufficient to form a protective chromia layer. Chrome–aluminizing is also used to improve protection, particularly at slightly higher temperatures. It has become the case, however, as temperatures increase in the pursuit of improved fuel efficiency, that more attention has been paid to the production of aluminide layers and the subsequent formation of alumina protective layers.

### 1.27.3.3.2 Aluminide coatings

Important applications of aluminide coatings arise in the protection of Co- and, particularly, Ni-based superalloys, since both form aluminide phases which fix high concentrations of aluminum as a surface layer, typically 30–70  $\mu\text{m}$  thick. The coatings can be produced from packs of either high or low aluminum activity. The former is processed at lower temperatures and the latter at higher temperatures in the typical range 800–1100 °C. High-activity aluminizing results in the formation of a  $\text{Ni}_2\text{Al}_3$  layer produced predominantly by inward diffusion of aluminum. Constituents of the alloy can become incorporated within this layer, which has relatively poor toughness. Improvements result in subsequent heat treatment to convert the higher aluminide to  $\text{NiAl}$ . Low-activity processing results directly in the formation of a  $\text{NiAl}$  layer, which forms principally by the outward diffusion of nickel. This layer is then relatively free of alloy constituents (but can contain pack residues

unless formed by vapor deposition above pack) and exists over a wide range of stoichiometry<sup>47</sup> as shown schematically in Figure 1. These coatings provide good resistance to Type-I hot corrosion and to high temperature oxidation through the formation and maintenance of a protective alumina layer. Their disadvantage is that they are relatively thin and, although having higher aluminum contents than the thicker MCrAlY overlay coatings, have a smaller total reservoir of aluminum. Loss of aluminum through the oxidation process as well as by interdiffusion with the substrate alloy limits their effectiveness after extended periods at high temperatures, say >1050 °C.

A particularly successful modification to aluminide coatings has been the incorporation of platinum into the coating by deposition of a thin layer,  $\sim 10\ \mu\text{m}$  thick, prior to the aluminizing stage. The  $\beta$  layer which is formed, again  $\sim 50\ \mu\text{m}$  thick, has the composition (Ni, Pt)Al with platinum contents of  $\sim 8\ \text{at.}\%$ . This phase can also exist over a wide range of aluminum and platinum contents.<sup>47</sup> The microstructure of such a coating is shown in the as-received condition in Figure 8(a) as a bondcoat (BC) within a thermal

**Figure 8** Cross-section of Pt-aluminide diffusion coatings. (a) In the as-received condition as a bondcoat (BC) in a TBC system showing the fully  $\beta$ -(Ni, Pt)Al layer and an extensive interdiffusion zone (IDZ) and (b) after 100h oxidation at 1100 °C showing partial transformation of the original  $\beta$  phase to  $\gamma'$  resulting from aluminum depletion. Courtesy of Miss F. Schenach.

barrier coating (TBC) system, which will be described later. It can be seen that there is also an extensive interdiffusion zone beneath the  $\beta$  layer. This contains a dispersion of phases rich in alloy constituents such as tantalum and titanium.

The addition of platinum to the  $\beta$ -phase appears to improve the oxide spallation resistance of the coatings, possibly by decreasing the segregation of sulfur to the oxide–metal interface.<sup>48,49</sup> It also decreases the chemical activity of aluminum<sup>47</sup> and then should be expected to decrease the extent of aluminum loss by interdiffusion with the substrate alloy. The experimental evidence is ambiguous, however, because platinum additions also seem to increase the principal diffusion coefficient of aluminum.<sup>47</sup> Continued exposures at high temperature will inevitably result in aluminum depletion as a consequence of both alumina formation and interdiffusion and this will cause phase transformation within the coating along the sequence

An example of a Pt-aluminized coating with partial transformation to the  $\gamma'$  phase after oxidation at 1000 °C for 100 h is shown in **Figure 8(b)**. It should be noted, though, that both phases have adequate aluminum contents to maintain a protective alumina layer.

### 1.27.3.3.3 Platinized coatings

An important variation on the conventional Pt-aluminized coatings described above is to omit the aluminizing stage in coating manufacture but to retain the step of platinum deposition and subsequent inward diffusion into the Ni-based superalloy. This approach was patented in 1999 by Rolls-Royce and Chromalloy UK<sup>50</sup> and has subsequently been developed to the stage of commercial deployment as BCs in TBCs – see later text for a description of these. Unfortunately, few of the results of the underlying research work supporting this development have appeared in the open literature.<sup>51,52</sup>

The key requirement of the coating is that it should be capable of forming and maintaining a protective alumina layer. It is not intuitively obvious, however, that this should be so because no aluminum is added and, as is recalled from **Section 1.27.1 and 1.27.2**, the Ni-based superalloy has borderline properties in this respect. Nevertheless, a 50- $\mu\text{m}$ -thick  $\gamma/\gamma'$  surface zone of enhanced aluminum concentration is formed indicating that there must be an outward

flux of aluminum from the alloy into this zone. Concentrations of aluminum in the Ni–Al–Pt coating need to be  $\sim 10$  wt%, that is, approximately twice the base alloy concentration, to stabilize the  $\gamma/\gamma'$  phase structure at 1100 °C.<sup>47</sup> The likely range of aluminum contents within the coating, shown schematically in **Figure 1**, is similar to that of MCrAlY coatings and will be sufficient both to form an initial alumina layer and to reheal this in the event of its failure (**Figure 2**). The apparent ‘uphill’ diffusion of aluminum out of the alloy into the coating, that is, its diffusion against its concentration gradient, can be explained again by the strong bonding between platinum and aluminum. It must mean that the chemical activity of aluminum within the coating is lower than that within the alloy so that the enrichment within the coating is simply a consequence of aluminum diffusing down its activity gradient. As recognized,<sup>47</sup> the coating has a replenishing capability by being able to transfer aluminum into itself from the alloy, as the continued growth of the alumina layer removes aluminum from its outer surface.

### 1.27.3.3.4 Silicide diffusion coatings

Silicide coatings have the potential of offering significant improvements in oxidation and hot corrosion resistance through the formation of a protective layer of silica. Siliconizing of iron and simple carbon steels was achieved by Fitzer in 1954<sup>53</sup> using pack cementation. These coatings were found to improve resistance to both Type-I and Type-II hot corrosion. They consist principally of an outer layer of ferrite containing up to  $\sim 10$  wt% Si and are susceptible to cracking during mechanical and thermal loading.<sup>54</sup> Silicon-rich coatings on Ni-based alloys have been achieved using chemical vapor deposition (CVD)<sup>55</sup> but there are concerns with the Ni–Si system over the presence of relatively low melting temperature eutectics. NiSi, in particular, forms an eutectic with Ni<sub>2</sub>Si which melts at 943 °C. More attractive approaches for iron- and nickel-based alloys are likely to involve the incorporation of silicon into chromized or aluminized layers.<sup>36,56</sup>

Direct reaction of silicon with the alloy substrate to form a high melting-point surface layer is of particular interest with molybdenum-,<sup>57</sup> niobium-,<sup>58</sup> and titanium-based<sup>57,59–62</sup> alloys. The last, in particular, are of current relevance in aeroengines because of their good density-compensated creep properties but are handicapped by poor long-term oxidation resistance.

A wide range of titanium silicides can be produced in sequential layers on the alloy surface by using a

cementation pack, as shown by Cockeram and Rapp.<sup>57,61</sup> These coatings can be  $\sim 100\text{ }\mu\text{m}$  thick and substantially improve oxidation resistance, particularly when doped with germanium when oxidation rates in the temperature range  $700\text{--}1000\text{ }^\circ\text{C}$  are similar to those for the growth of silica itself (Figure 9). Protection is maintained even under thermal cycling but the layers are brittle and cracking should be expected. This is accentuated by the thickness of the coating which increases the probability of crack-like initiating defects being present.

Thinner coatings ( $\sim 1\text{--}10\text{ }\mu\text{m}$ ) can be produced by siliconizing, in which the test piece is buried in silicon powder, at temperatures between  $800$  and  $1100\text{ }^\circ\text{C}$ .<sup>59,60</sup> Higher temperatures in this range favor the formation of the  $\text{Ti}_5\text{Si}_3$  phase rather than  $\text{TiSi}_2$  as the outermost layer produced in the cementation pack.<sup>57,61</sup> These thin  $\text{Ti}_5\text{Si}_3$  layers were uncracked and the layers again conferred significant improvements in oxidation resistance of the underlying Ti-rich alloy, as can be appreciated from Figure 9. A rather novel approach<sup>62</sup> to producing a thin,  $1\text{--}2\text{ }\mu\text{m}$ , layer of  $\text{Ti}_5\text{Si}_3$  is to use reaction (B) below to transport silicon to a Ti–Al test piece *via* gaseous SiO.

The subsequent reaction [9] produces the silicide:

The overall reaction is

This reaction will only proceed in the direction shown at low oxygen partial pressures, calculated by Gray *et al.*<sup>62</sup> at  $7.7 \times 10^{-22}$ . This seems to have been achieved in a sealed silica capsule, evacuated from an argon atmosphere, without the use of extraneous oxygen getters, such as titanium chips, but by using the  $\alpha_2$  phase of the alloy as an intrinsic getter. As with the above, a substantial improvement in oxidation resistance, a factor 5 in weight gain in this case, was achieved over the uncoated Ti–Al control over the test duration of 500 h at  $900\text{ }^\circ\text{C}$ . The parabolic rate constants of the more protective coatings are plotted in Figure 9 and compared with the behavior of unalloyed titanium<sup>63</sup> and pure silicon.<sup>64</sup> It can be seen that only the Ge-doped coatings actually achieve the level of protection expected of a pure silica layer.

Broadly similar behavior to the  $\text{Ti}_5\text{Si}_3$  coatings has been found by Taniguchi *et al.*<sup>65</sup> for the bulk phase. In this case, rutile ( $\text{TiO}_2$ ) had formed above the silica layer and clearly contributed to the weight

**Figure 9** Parabolic rate constants for some silicide-coated titanium-rich alloys compared with the behavior of unalloyed titanium and silicon.

gain of the specimen. An implication is that the beneficial influence of Ge-doping (Figure 9) arises by limiting the transport of titanium through the silica layer.

### 1.27.3.4 Thermal Barrier Coatings

When discussing the need for high temperature coatings in Section 1.27.1, emphasis on placed solely on achieving adequate oxidation and corrosion resistance. However, under modern turbine conditions and in other applications, such as diesel engines, it can also be necessary to protect the substrate alloys from combustion temperatures by means of TBCs. This developmental trend for aeroengines and associated Ni-based superalloys is shown in simplified form in Figure 10.

It can be seen how in the first 20 years or so, blade alloys had adequate properties in the wrought and unprotected form to satisfy turbine requirements. In the early 1960s, a significant change in blade design permitted the use of some intake air to provide cooling and this increased the turbine entry temperature (TET) significantly above the inherent capabilities of the substrate alloys. During this period from 1940 to approximately 1990, successive generations of superalloys were developed with improved mechanical properties and, hence, higher temperature capabilities. This has been shown simply as a linear trend in Figure 10 but more details can be found elsewhere.<sup>1</sup> The main change during this period was to move from wrought to cast, directionally-solidified structures.

The most recent development is the use of cast, single-crystal alloys, such as CMSX-4 (see Table 1), for blades which remain cooled and also are now coated with TBC systems. The use of these can improve engine efficiency and can also extend service lifetimes.<sup>66,67</sup> This same general developmental trend is mirrored in land-based turbines although TETs in these cases tend to be lower and the moves toward TBC usage lag behind those of aeroengines. A cross-section of a typical TBC system is shown schematically in Figure 11.

A TBC system consists of the outer thermal barrier topcoat which is attached to the alloy substrate by means of a mechanically-compliant, oxidation-resistant BC. The topcoat is generally zirconia, containing ~7–8 wt% yttria. This addition provides partial stabilization of the tetragonal (and cubic) zirconia phases and avoids the volume changes associated with the formation of the monoclinic phase. This yttria-stabilized zirconia (YSZ) layer (sometimes termed yttria partially stabilized zirconia (YPSZ)) has a low thermal conductivity,  $\sim 1 \text{ W m}^{-1} \text{ K}^{-1}$ , which is approximately an order of magnitude lower than that for alumina. It means that for cooled turbine blades, a temperature drop of perhaps  $150^\circ \text{C}$  can be obtained across a 250–300- $\mu\text{m}$ -thick topcoat during service which provides considerable benefit to the load-bearing capability of the Ni-based superalloy. It needs to be emphasized, however, that the YSZ topcoat is permeable to oxygen and will not provide oxidation protection. This is achieved by means of the BC which is intended to be alumina-forming and can be based on

**Figure 10** A comparison of the historical increase in turbine entry temperature (TET) for aeroengines and the associated temperature capability of the alloys used for turbine blades.

**Figure 11** Schematic cross-section of a thermal barrier coating system.

**Figure 12** Cross-section of a typical land-based TBC coating system consisting of an air plasma sprayed (APS) YSZ topcoat with a MCrAlY BC<sup>68</sup> on an IN738 Ni-based superalloy substrate. Note the relatively rough BC surface and the limited interdiffusion zone compared with the TBC system shown in Figure 8(a).

one of the MCrAlY overlays discussed previously or on diffusion coatings of the Pt-aluminide or platinized variants. The oxidation of these BCs forms a layer of thermally grown oxide (TGO) over time between the BC and TBC topcoat as shown schematically in Figure 11. As will be discussed in some depth in Section 1.27.5, the formation of the TGO plays a significant role in the failure by spallation of the TBC.

TBC systems used in practice on Ni-based superalloys for turbine applications tend to be of two distinct types. For large, land-based units, a system consisting of a MCrAlY BC, deposited by any of the processes discussed previously, with a YSZ topcoat produced by APS is usually used. An example of this system is shown in Figure 12. In smaller machines, such as aeroengines or, increasingly, small land-based turbines, YSZ layers deposited by electron-beam physical vapor deposition (EB-PVD) are favored. These TBC systems can use MCrAlY BCs also but more typically have Pt-aluminide or, in Rolls-Royce

aeroengines, platinized diffusion coatings. A typical cross-section of a system consisting of an EB-PVD topcoat and a Pt-aluminide diffusion BC is shown in Figure 8(a). The columnar nature of the EB-PVD topcoat is evident and can be contrasted with the splat structure of that produced by APS. A much more extensive interdiffusion zone than in the MCrAlY system is also formed during coating manufacture.

To date, the commercial exploitation of TBC systems has been dominated by applications using Ni-based alloys but there is also foreseeable potential for their use on other high temperature structural materials such as the Ti–Al series. Significant progress has already been made in the production of aluminide diffusion coatings on Ti-based alloys<sup>69–71</sup> and recently these have been used as a BC under an APS YSZ topcoat in a TBC system.<sup>72</sup>

## 1.27.4 Case Study I: Oxidation and Lifing of MCrAlY Overlays

### 1.27.4.1 Protective Oxidation

In the initial stages of exposure of a complex alloy such as the (Ni, Co)CrAlYs, all constituents which can oxidize will do so and nonprotective oxides such as NiO together with spinels such as NiCr<sub>2</sub>O<sub>4</sub> are likely to form. Eventually, however, a continuous  $\alpha$ -alumina layer will develop underneath these oxides and oxidation rates will rapidly decrease. The formation of metastable aluminas, even at the relatively low temperature of 950 °C, was not found in a study<sup>73</sup> using *in situ* high temperature XRD on a CoNiCrAlY coating. This transitional behavior may not be an issue with these systems at relevant operating temperatures although with FeCrAlY alloys at the slightly lower temperatures of 900 and 925 °C, the transition from  $\theta$ - to  $\alpha$ -alumina took tens of hours.<sup>74</sup>

The growth kinetics of the  $\alpha$ -alumina layer on MCrAlY-type alloys have been variously reported to be parabolic (eqn. [1])<sup>75,76</sup> or subparabolic<sup>77</sup> as in the general eqn. [11] for increase in oxide thickness,  $b$ , with exposure time,  $t$ , at a constant temperature.

$$b = b_0 + k_n t^{1/n} \quad [11]$$

Here,  $b_0$  is the preexisting oxide thickness at  $t = 0$ ,  $n$  is a time-invariant numerical constant, and  $k_n$  is the corresponding rate constant. Ideal parabolic conditions exist when  $b_0 = 0$  and  $n = 2$  (eqn. [1]) but subparabolic kinetics obtain when  $n > 2$ . The reasons for the differences in kinetics are poorly understood

although there are considerable implications for the longevity of the coatings. Subparabolic kinetics can arise, in principle, as a result of an increase with time of compressive growth stress within the oxide layer.<sup>38,78</sup> They will also arise<sup>79</sup> if oxide grain size increases during exposure and diffusion of reactive species occurs principally by grain boundary diffusion. It is also feasible, particularly with a stoichiometric compound such as alumina, that the gradual incorporation of coating or alloy (minor) constituents affects any doping of the oxide layer so as to decrease diffusion rates progressively with time. Apparent subparabolic kinetics will also occur in those systems and exposure conditions in which metastable alumina forms and transforms over time to the  $\alpha$  phase.<sup>80</sup> The situation is unclear and, for present purposes, it will be assumed that the  $\alpha$ -alumina layer grows parabolically with time with  $h_o = 0$  and  $n = 2$  in eqn. [11]. This assumption leads to conservative estimates of coating lifetimes.

The temperature dependence of the parabolic rate constant for the growth of a protective  $\alpha$ -alumina layer on various coating-type alloys is shown in Figure 13,<sup>75,76</sup> but expressed in terms of mass gain,  $\Delta m$ , per unit surface area. A reasonable mid-range expression for the rate constant,  $k'_p$ , from Figure 13 is

$$k'_p = 2.68 \times 10^4 \exp\left(-\frac{275\,000}{8.314T}\right), \text{mg}^2 \text{cm}^{-4} \text{s}^{-1} \quad [12]$$

where  $T$  is absolute temperature and the mass gain has been expressed in the more common units of  $\text{mg cm}^{-2}$ . This equation can be expressed in terms of the parabolic rate constant  $k_p$ , which uses oxide thickness rather than mass gain, by means of eqn. [13].

$$k_p = \left[ \frac{M_{\text{ox}}}{3M_o\rho_{\text{ox}}} \right]^2 k'_p \quad [13]$$

Here,  $\rho_{\text{ox}}$  is the density of  $\alpha$ -alumina (taken as  $4000 \text{ mg cm}^{-3}$ ),  $M_{\text{ox}}$  is the molecular mass of alumina and  $M_o$  is that of oxygen; the factor three arises because there are three oxygen atoms in  $\text{Al}_2\text{O}_3$ . This conversion equates  $1 \text{ mg cm}^{-2}$  mass gain to an  $\sim 5.3 \mu\text{m}$  thick layer of  $\alpha$ -alumina. Using eqn. [13] to substitute into eqn. [12] then gives:

$$k_p = 7.56 \times 10^{-7} \exp\left(-\frac{275\,000}{8.314T}\right) \text{m}^2 \text{s}^{-1} \quad [14]$$

The protection offered by the alumina layer can be appreciated by using eqn. [14] in eqn. [1] to show that the oxide thickness after 30000 h at  $1000^\circ\text{C}$  is still only  $\sim 20 \mu\text{m}$ . This corresponds to a section loss,  $x_h$ , of the coating of<sup>38</sup>

**Figure 13** Parabolic rate constants for the formation of alumina on coating-type alloys.<sup>76</sup>

$$x_h \approx \frac{b}{\phi} \approx \frac{20}{1.28} \approx 15.6 \mu\text{m} \quad [15]$$

where  $\phi$  is the Pilling–Bedworth ratio for alumina (1.28). This level of loss in an MCrAlY coating some  $200 \mu\text{m}$  thick after this exposure period would be excellent behavior but, unfortunately, other degradation processes also occur which limit lifetimes. Principal among these is the loss of aluminum from the coating and the consequences of this. Depletion will occur as a result of selective oxidation, as described in Section 1.27.2.2, and will increase with time at temperature. In addition, it will be exacerbated by spallation or cracking (and rehealing) of the protective oxide layer, geometrical factors, internal oxidation, and interdiffusion with the substrate alloy. All of these factors will be considered in this section.

#### 1.27.4.2 Spallation and Cracking of the Protective Alumina Layer

Spallation and cracking of the protective oxide layer results from the generation of strains and associated stresses arising from the oxide growth process,

from temperature changes or imposed upon the component. The issues are particularly complex since they depend on the nature of the oxidation process (the balance between growth by cation or anion fluxes), on the curvature of the substrate and on the elastic, plastic and, particularly, creep properties of the respective layers of the coating system. A background review is available<sup>38</sup> and phenomenological approaches to failure which combine strains from multiple sources have also been developed.<sup>81–83</sup> These predictive approaches have been formulated specifically for TBC systems but contain general principles.

This chapter emphasizes solely the influence of thermal strains in producing oxide spallation from a MCrAlY substrate in order to establish mechanisms. Strains deriving from oxide growth will be significant only if creep relaxation rates are low or, on curved surfaces, if the oxide thickness is of similar magnitude to the local radius of curvature.<sup>38</sup> For now they are neglected but, if significant, can simply be introduced as an additive term.<sup>82</sup> The implication is that the alumina–MCrAlY interface is sensibly flat, that is, there are no locations where the local radius of curvature is of similar magnitude to the oxide thickness. During cooling there are then negligible out-of-plane strains, provided the oxide remains adherent, but a substantial biaxial compressive in-plane strain can develop within the oxide layer. If elastic conditions are assumed, this strain corresponds to an in-plane oxide stress,  $\sigma_{ox}$ , given by<sup>84</sup>:

$$\sigma_{ox} = \frac{E_{ox} \Delta T (\alpha_m - \alpha_{ox})}{(1 - \nu) \left(1 + \frac{E_{ox} b}{E_m w}\right)} \quad [16]$$

Here,  $\Delta T (=T - T_{ox})$  is the temperature drop, taken as a negative quantity,  $E_{ox}$  and  $E_m$  are the Young's moduli of, respectively, oxide and metal;  $\alpha$  is the corresponding linear thermal expansion coefficient;  $\nu$  is the Poisson's ratio, assumed to be the same for oxide and metal;  $b$  is the oxide thickness, and  $w$  is half the specimen thickness. For thin oxides

relative to the metal substrate, the equation can be simplified to (compare eqn. [7]):

$$\sigma_{ox} = \frac{E_{ox} \Delta T (\alpha_m - \alpha_{ox})}{(1 - \nu)} \quad [17]$$

It is also reasonable to assume that the underlying superalloy is much thicker than the coating and, of course, the oxide so that the alloy's dimensional changes are imposed upon the oxide. This means that in eqn. [17], the expansion coefficient,  $\alpha_m$ , should be that for the superalloy rather than for the coating. Using representative values of,  $\nu = 0.3$ ,  $E_{ox} = 387$  GPa,  $\alpha_{ox} = 7.9 \times 10^{-6} \text{ K}^{-1}$ , and  $\alpha_m = 15.0 \times 10^{-6} \text{ K}^{-1}$  in eqn. [17] predicts a residual in-plane oxide stress of  $\sim -3.9$  GPa after a temperature drop of  $1000^\circ\text{C}$ . Values of stress of this magnitude have been measured in related alloys and coatings.<sup>68,85,86</sup> Since the values of expansion coefficients and Young's modulus are assumed to be independent of temperature, the elastic oxide stress varies proportionately with temperature change and will be tensile for temperature increases above the oxidation temperature.

Spallation under in-plane compression can occur by two nominally distinct routes depending on the relative strengths of oxide and oxide–coating interface,<sup>38,39</sup> as shown schematically in Figure 14. The critical stress for buckling of the oxide layer (Figure 14(a)) can be obtained from standard text<sup>87</sup> and converted<sup>38</sup> to a critical temperature drop,  $\Delta T_b$ , of

$$-\Delta T_b = \frac{1.22}{(1 - \nu^2)(\alpha_m - \alpha_{ox})} \left(\frac{b}{R}\right)^2 \quad [18]$$

where the symbols have the same meaning as previously and  $R$  is the radius of the circular zone of prior decohesion at the oxide–coating interface. It can be appreciated that for a given value of  $R$ , the temperature drop required to effect buckling increases with oxide thickness. For typical values of the various parameters, the zone diameter needs to be approximately at least  $20\times$  the thickness of the oxide layer

**Figure 14** Spallation of the oxide layer under in-plane compression from the metallic MCrAlY substrate can occur by either (a) a buckling or (b) a wedging process.

before the buckle configuration can develop. Thus, for a typical oxide thickness of 5  $\mu\text{m}$ , a circular interfacial zone of some 100  $\mu\text{m}$  would be required. This is a problematic issue since such large areas of decohesion are not seen at the alumina-MCrAlY interface in these simple overlay coatings. The intrinsically good adherence of the alumina layer is related to the addition of yttrium into these coatings which appears to mitigate the potentially harmful effects of sulfur segregation in lowering interface adhesion.<sup>88,89</sup>

In the presence of good adhesion between oxide and coating, a thick protective layer can develop but this, as found on related systems, still contains porosity and crack-like defects.<sup>90,91</sup> At some critical value of the compressive thermal stress generated during the cooling transient, a shear crack can be initiated from one or more of these defects, as shown schematically in Figure 14(b). Continued cooling and contraction of the oxide layer will produce further shear on the crack-like surface and the development of out-of-plane tensile stresses at the oxide-coating interface. A consequence is that a wedge crack will grow along this interface as cooling continues and may cause spallation of the overlying oxide layer. Extensive finite-element (FE) modeling of this wedging process has now been undertaken for chromia and alumina layers on various metallic substrates.<sup>92–94</sup> A consistent result from this work is that the growth rate of the interfacial wedge crack is significantly retarded during cooling as a result of the relaxation of crack-tip stresses by creep of the adjoining metal. Some results<sup>93</sup> for a 5- $\mu\text{m}$ -thick alumina layer on Haynes 214 are given in Figure 15. They show that the wedge crack nucleates quickly but its growth rate is then stopped until some lower temperature at which rapid propagation occurs over a narrow temperature range. This period of quiescence corresponds to the period of significant stress relaxation by alloy creep and its extent decreases with increased cooling rate, as shown.

The general behavior shown in Figure 15 can be approximated by the dashed horizontal and vertical lines superimposed, for clarity, only on the FE results for a cooling rate of  $10^4\text{ }^\circ\text{C h}^{-1}$ . They can be interpreted as showing that the oxide remains adherent to the alloy or coating until a critical temperature drop,  $\Delta T_c$ , at which stage the stored strain energy,  $W^*$ , per unit volume in the oxide layer is sufficient to produce decohesion of the oxide-metal interface. For a thin planar biaxially strained oxide layer of thickness  $b$ , the strain energy in the oxide layer per unit area of

**Figure 15** Finite-element predictions of the kinetics of interfacial wedge crack growth for an alumina layer on Haynes 214 cooled from 1100  $^\circ\text{C}$  at the rates shown. The dashed line reflects ideal behavior for spallation to occur at a critical value of oxide strain energy.

oxide-metal interface at a temperature drop  $\Delta T$  is given as<sup>95</sup>:

$$bW^* = bE_{\text{ox}}(1 - \nu)(\Delta T)^2(\alpha_m - \alpha_{\text{ox}})^2 \quad [19]$$

Equating this to the fracture energy,  $\gamma_F$  of unit area of interface gives the critical temperature drop for spallation as:

$$-\Delta T_c = \left[ \frac{\gamma_F}{bE_{\text{ox}}(\alpha_m - \alpha_{\text{ox}})^2(1 - \nu)} \right]^{1/2} \quad [20]$$

This shows that the critical temperature drop decreases with oxide thickness, that is, spallation becomes easier for thicker oxides which is a common observation. It contrasts with the buckling mode (eqn. [18]) which becomes more difficult with increasing oxide thickness.

In applying eqn. [20] for prediction it should be noted that the fracture energy is an effective value since most of the strain energy is lost by creep relaxation during the cooling transient.<sup>92–94</sup> Its value can be obtained from eqn. [20] using the FE predictions of  $\Delta T_c$  and is always larger than the intrinsic fracture energy of the interface when relaxation processes are present. Thus, for the example shown in Figure 15,  $\gamma_F$  is calculated to be  $\sim 33\text{ J m}^{-2}$  for the higher cooling rate and  $\sim 62\text{ J m}^{-2}$  for the lower. Using a similar approach for a free-standing NiCrAlY coating,<sup>93</sup> the values of the effective fracture energy shown in

**Table 3** Estimated effective fracture energies,  $\gamma_F$ , for the spallation of a 5- $\mu\text{m}$ -thick alumina layer from a free-standing NiCrAlY coating<sup>92</sup>

Cooling rate ( $^{\circ}\text{C h}^{-1}$ ; $^{\circ}\text{C s}^{-1}$ )	Computed $\Delta T_c$ ( $^{\circ}\text{C}$ )	$\gamma_F$ ( $\text{J m}^{-2}$ )
$10^2$	745	40
$10^3$	620	28
$10^4$	550	22
$10^5$	382	10
$10^6$	314	7

**Table 3** are obtained as a function of cooling rate. This decrease of  $\gamma_F$  with increasing rate reflects the decreased contribution from creep relaxation and shows that no unique value of the fracture energy can be assumed. It is possible, however, to interpolate between these results for any given conditions within the range shown. The values of  $\gamma_F$  given in the table are typically 10–100 greater than the likely intrinsic interfacial fracture energy but are of similar magnitude to those measured by blister testing<sup>96</sup> and spallation<sup>93,94,97,98</sup> on other systems.

This discussion has highlighted the benefits of stress relaxation within the coating to the spallation resistance of the oxide during a simple cooling transient. It should not necessarily be generalized from this, however, that weak coatings should be preferred over strong. An important consideration is that creep relaxation during thermal cycling can generate a mechanical hysteresis loop<sup>94,99</sup> which can place the oxide layer into in-plane tension on the return to temperature. Consequent tensile cracking will, of course, impair the protective function of the oxide layer. Strong coatings are also desirable to maintain mechanical stability in rapidly rotating components. The balance of creep properties between high and low strength will depend on the application, for example, the magnitude of external stresses, the frequency of thermal cycling, the rate of change of temperature, and the presence of hold periods within the creep regime.

### 1.27.4.3 Aluminum Depletion

#### 1.27.4.3.1 Uniform depletion

The second main form of coating degradation is through the loss of aluminum and the consequent inability to maintain and reform the protective alumina layer. A general discussion of the depletion occurring as a result of the selective oxidation of aluminum has been given in [Section 1.27.2.2](#). It is

shown in that section, how the aluminum concentration can be decreased beneath the oxide but that the aluminum reservoir within the bulk of the coating could maintain concentrations sufficiently to ensure reformation of the alumina layer in the event of its spallation or cracking. Nevertheless, the depletion of aluminum by selective oxidation will destabilize Al-rich phases in the vicinity of the surface oxide. In particular, dissolution of the  $\beta$ -NiAl phase will occur in a zone near the alumina layer<sup>100,101</sup> and, as expected for parabolic oxidation kinetics, the depth of this  $\beta$ -free zone will thicken parabolically with time. In addition, loss of aluminum by interdiffusion with the substrate can also result in the formation of a  $\beta$ -free zone at this inner interface. With continued exposure, the entire coating can become free of the  $\beta$ -phase and this has been used as a failure condition for the coating.<sup>100</sup> This is a useful pragmatic approach but is conservative since sufficient aluminum will usually still be present to provide a rehealing capability.

Even so, substantial exposure periods can be obtained while still retaining some  $\beta$ -phase. Anton *et al.*,<sup>101</sup> for example, find a total  $\beta$ -depletion zone, from inner and outer coating surfaces, of 160  $\mu\text{m}$  in a 250- $\mu\text{m}$ -thick LPPS CoNiCrAlY coating after 10000 h at 1000  $^{\circ}\text{C}$ . This particular coating contained only 8 wt% Al but exhibited substantial interdiffusion with the IN738LC alloy substrate and formation of Kirkendall voids within the interdiffusion zone (IDZ). The extent of  $\beta$  depletion was decreased, as expected, by increasing the aluminum content to 12 wt% in a NiCoCrAlY coating but rhenium additions also decreased the extent of interdiffusion. In this case the total  $\beta$ -depletion zone was only  $\sim 75 \mu\text{m}$  after 10 000 h at 1000  $^{\circ}\text{C}$ .<sup>101</sup>

Although the extent of aluminum depletion resulting from selective oxidation can be predicted based on the concepts outlined in [Section 1.27.2.2](#), it is much more difficult to model the interdiffusion process. Analytical and numerical attempts have been made for MCrAlY systems<sup>83,102</sup> but it is difficult to deal with diffusion and concurrent precipitation without knowing the appropriate interaction terms for the diffusion coefficients or, equivalently, the chemical activities of the diffusing species. Taylor, *et al.*,<sup>102</sup> for example, report how the diffusion of aluminum from a LPPS CoNiCrAlY coating into a CM186 substrate alloy, in the early stages of exposure at 1200  $^{\circ}\text{C}$ , is limited by the formation of Al-rich phases, associated with tantalum, within the IDZ. With continued exposure and further aluminum

**Figure 16** Enhanced aluminum depletion measured in individual diffusion cells in an APS CoNiCrAlY coating.

depletion within the coating, these phases dissociate and act as a reservoir to resupply aluminum back into the coating. These counter-flows of diffusive flux reflect the changing aluminum activities within the coating and IDZ. They emphasize that, in such complex situations, modeling using single-valued diffusion coefficients and chemical potential gradients approximated by gradients in concentration can lead to erroneous results.

Interesting future developments to limit inter-diffusion are likely to involve the control of aluminum chemical activity within the coating<sup>103</sup> or the use of diffusion barriers such as  $\alpha$ -Cr or Re-based alloys.<sup>104</sup>

#### 1.27.4.3.2 Diffusion cells and chemical failure

In practice, exceptions to the ideal condition of uniform depletion will exist. These include the diffusional isolation of volumes of the coating as a result of internal oxidation or geometric factors. As highlighted in Figure 3, MCrAlY coatings deposited by plasma spraying in air (APS) are of relatively low density as a result of oxidation of the sprayed particles during coating formation. Bonding between the splats within the coating is impaired and internal oxidation at the splat surfaces can continue during subsequent exposure. APS and even HVOF coatings probably also suffer from this but to a lesser extent. The alumina layers formed internally in APS MCrAlY coatings have been shown<sup>105</sup> to act as diffusion barriers which isolate the splat volume from the reservoir of aluminum in the remainder of the coating. As a consequence, aluminum depletion within the relatively small splat volume occurs at a much greater rate than would be expected for the coating as a whole. This is shown in Figure 16 for an APS CoNiCrAlY coating oxidized in air at 1100 °C.<sup>105</sup> Here the measurements of aluminum concentration were obtained across separate diffusion cells which were located at the surface of the coating and bounded around their surface by an alumina layer. The lines in the figures are predictions from eqn. [21] which considers the cell to be approximated as a long 2-dimensional slab, on both flat surfaces on which alumina grows parabolically.

The points are measured using SEM/EDS and the solid line is the best-fit solution to eqn. [21] using the values shown for  $D$  and  $k_p$ . See text for more details. The dashed line is the expected depletion profile, using the same values of  $D$  and  $k_p$ , if diffusion cells were absent. Oxidation was performed in air for (a) 4 h, (b) 4 h, and (c) 100 h.<sup>105</sup>

$$C = C_b - \frac{50}{\phi} \left( \frac{\pi k_p}{D} \right)^{1/2} \sum_{n=0}^{\infty} \left[ \operatorname{erfc} \left( \frac{2nw+x}{2(Dt)^{1/2}} \right) + \operatorname{erfc} \left( \frac{2(n+1)w-x}{2(Dt)^{1/2}} \right) \right] \quad [21]$$

Here,  $C$  is the aluminum concentration in at.%,  $C_b$  is the initial value within the cell,  $D$  is the aluminum interdiffusion coefficient,  $2w$  is the cell width,  $x$  is the distance from the oxide–metal interface, and  $t$  is the exposure time. The predictions were made using a single-valued interdiffusion coefficient  $2.4 \times 10^{-14} \text{ m}^2 \text{ s}^{-1}$  (N.B. the sites were remote from any interdiffusion effects from the substrate) consistent with measurements on NiCrAl<sup>106</sup> and CoCrAl<sup>107</sup> systems. The corresponding  $k_p$  values to give the observed fit vary within a factor 2 but lie within the data spread of Figure 13 (shown there in terms of mass gain). The expected depletion profile without diffusion cells is shown by the dashed line. The agreement with the data is good and confirms that oxidation is continuing at similar rates at both the external and internal surfaces in these coatings. It can be seen that depletion is much more pronounced in the small cell of Figure 16(b) than in the larger one of Figure 16(a) even after 4 h at 1100 °C. After 100 h exposure, aluminum has been essentially consumed in the 55  $\mu\text{m}$  cell, Figure 16(c).

The decrease in aluminum concentration can make these cell volumes susceptible to chemical failure (CF) at which stage fast-growing nonalumina oxides will form. A framework theory of CF can be found elsewhere.<sup>108</sup> The cell will be susceptible to mechanically induced chemical failure (MICF) when the aluminum concentration anywhere within it (usually, at the center plane) falls below that needed to reform the alumina layer should the original crack or spall. Intrinsic chemical failure (InCF), unlike MICF, is a thermodynamic boundary at which the aluminum concentration at the oxide–metal interface falls to that below which alumina can be reduced by another of the coating constituents, chromia for example. This critical concentration is very close to zero for the reduction of alumina by chromium but there is experimental evidence for the formation of Cr-rich oxides beneath an alumina layer in NiCrAlY coatings.<sup>109</sup>

A CF map for MCrAlY coatings can be constructed using eqn. [21] as shown in Figure 17. The calculations were performed using  $D = 2.4 \times 10^{-14} \text{ m}^2 \text{ s}^{-1}$ , as above, and a mid-range value of  $k_p = 9.0 \times 10^{-17} \text{ m}^2 \text{ s}^{-1}$ . The threshold line for

**Figure 17** A chemical failure (CF) map for a MCrAlY coating ( $M = \text{Co, Ni}$ ). The left-hand ordinate refers to exposure times at 1100 °C but the oxide thickness of the right-hand ordinate is independent of temperature.

initiating CF is relevant to the MICF condition assuming a critical aluminum concentration of 5 at.%. The exposure times shown as the left-hand vertical axis refer to 1100 °C but the oxide thicknesses (right-hand axis) apply at other temperatures also. Clearly, small cells are susceptible to early MICF leading to the consumption of the entire cell volume with the formation of porous and friable nonprotective oxides. For dense coatings, however, for example those produced by LPPS, internal oxidation is negligible and small diffusion cells do not form.<sup>110</sup>

MCrAlY coatings produced by spraying tend to have convoluted surfaces consisting of protuberances with dimensions relating to those of the original sprayed particles. They may also be postprocessed to change this topography but usually have a significant residual surface roughness. The significance is that a surface protuberance will have a surface-to-volume ratio larger than that of a flat coating. Aluminum depletion will then occur at an enhanced rate and early CF of the protuberance can be expected. Calculation of the rate of depletion is difficult to undertake analytically because the protuberance is not isolated from the bulk of the coating, as with the diffusion cells discussed earlier. Some resupply of aluminum will occur *via* the neck of the protuberance. Useful progress in prediction can be made, however, using numerical finite-difference methods and an example of some results, obtained using the 2-dimensional ODIN (Oxidation and INterdiffusion) code, is shown in Figure 18. These results apply to a

**Figure 18** Finite-difference predictions of the Al depletion produced in a surface protuberance of a MCrAlY coating after oxidation at 1100 °C for 1 h. The left-hand and top axes give distances in microns. The right-hand axis gives the aluminum concentration corresponding to the iso-concentration lines drawn on the figure. Courtesy of Dr. W.M. Pragnell.

100  $\mu\text{m}$  thick MCrAlY coating oxidized at 1000 °C for 1 h but with, for purposes of illustration, a relatively low initial concentration of 10 at.% Al. It can be appreciated that selective oxidation to form the alumina layer causes a significant decrease in aluminum content at the surface of the bulk coating with concentration increasing with distance from this interface. More details can be found elsewhere.<sup>111</sup> This level of depletion is similar to the schematic line for an uncoated alloy, of similar aluminum content, shown in Figure 2. In this particular example, there remains sufficient aluminum at depths of  $\sim 10\ \mu\text{m}$  to reform the protective alumina layer. This contrasts with the situation within the protuberance, however, where concentrations have dropped everywhere to  $< 1$  at.% after 1 h exposure. Early MIF of this is then likely and, indeed, was observed.<sup>111</sup> This failure time is somewhat less but of similar magnitude to that shown for diffusion cells in Figure 17.

## 1.27.5 Case Study II: Oxidation-Induced Failure of TBC Systems

### 1.27.5.1 Failure Times under Oxidizing Conditions

An overview of TBC systems and principal types has been given in Section 1.27.3.4. They are an essential part of present-day strategies to operate high temperature machinery, particularly aeroengines and gas turbines, with increased fuel efficiency and

longevity. In order to achieve this and to develop the full potential of TBC systems safely and reliably, it is necessary to understand and predict the degradation and failure processes within the system leading to spallation of the insulating topcoat. As a consequence, a tremendous amount of research activity has been undertaken worldwide, particularly in the last decade, to try and achieve these goals. At the time of writing, success has been elusive although large amounts of experimental data have been produced and a plethora of theoretical models have been suggested. It is beyond the scope of this present work to provide a detailed and comprehensive review of this large body of work which is often contradictory. Rather, a personal view will be presented which will attempt to identify key experimental observations and materials' properties and favor theoretical models which are consistent with these.

In some applications, for example, on rotating blades in gas turbines, TBC systems will experience mechanically-imposed strains in addition to those developed by the oxidation process. As discussed in relation to MCrAlY overlay coatings (Section 1.27.4.2), it may be feasible to sum these various strains and define a critical total value at which TBC failure will occur.<sup>81–83</sup> The approach is phenomenological in that no detailed mechanisms of failure are considered. It is, therefore, difficult to generalize complex situations where strains may be tensile or compressive and may act in different directions at different locations within the TBC system. Nevertheless, the approach does attempt to address the difficult subject of the interaction between applied external stresses and those produced by oxidation. For present purposes, however, as earlier with MCrAlY overlays, the intention is to examine only the role of oxidation and thermal loading in TBC failure.

It was pointed out in Section 1.27.3.4 that oxygen can penetrate the YSZ TBC layer and oxidize the underlying BC. The TGO, designed to be alumina, forms as an interlayer between the topcoat and BC as shown schematically in Figure 11. The development of this layer has been implicated in TBC spallation for many years and a simple failure criterion, used in practice, is to assume that spallation will occur at a critical TGO thickness. As shown in Figure 19, this can be a useful approach.

The time-to-failure data shown in Figure 19 derive from previous compilations,<sup>112,113</sup> but have been simplified to distinguish only between the common types of TBC system in commercial use: Pt-aluminide/EB-PVD YSZ, MCrAlY/EB-PVD YSZ, and MCrAlY/APS YSZ. Results on experimental

systems, which can show improved behavior to the above, have been omitted from this graph intentionally although they are prominent in current research literature. These include the use of platinum over- and under-layers to MCrAlY BCs,<sup>114</sup> preoxidation of MCrAlY BCs,<sup>115,116</sup> polishing of the BC surface,<sup>117</sup> and platinized BCs<sup>51,52</sup> see also [Section 1.27.3.3.3](#)). This body of work is of interest and may point the way to future improvements in TBC systems. The results have been omitted from [Figure 19](#) simply because they add other variables which will confuse the trends present in the failure-life compilation for conventional systems.

The data shown in [Figure 19](#) include results from tests ranging from nominally isothermal exposure to those using hourly thermal cycles, for which the accumulated time at peak temperature is used in the figure. A striking feature of the results is the very large scatter in lifetime – a factor 10 – at any given temperature. Within this scatter, there appears to be no systematic difference in behavior between the coating types or with the frequency of cycling.<sup>112</sup> This is a valuable working premise with which to find a path through the diverse competing models of failure. The solid line in the figure is the expected behavior if topcoat spallation occurred at a critical TGO thickness of 4  $\mu\text{m}$ . It is calculated from

eqn. [14], assuming an initially bare BC surface. It should be noted, though, that those systems with an EB-PVD topcoat will usually have a preformed alumina layer,  $\sim 0.5 \mu\text{m}$  thick on the BC surface. The agreement with the solid-line prediction is, nevertheless, quite reasonable and supports the use of this simple criterion as a pragmatic lifing method. It also supports the view,<sup>118,119</sup> that time and temperature are the principal parameters affecting lifetimes. The scatter can then be thought of as reflecting the underlying variability in the oxidation process together with the influence of uncontrolled variables, many of which are likely to arise from the manufacturing process. These will include BC surface roughness,<sup>112,113,117</sup> defects within the topcoat which may initiate interfacial cracks,<sup>120</sup> segregation of elements such as titanium from the substrate alloy,<sup>52</sup> and variable sulfur contents, particularly in Y-free BCs and alloys.<sup>91,121</sup>

### 1.27.5.2 Failure Characteristics

The failure times plotted in [Figure 19](#) refer to the loss of typically 20% or more of the area covered by the YSZ topcoat. Often this occurs by the spallation of the topcoat in sheets measuring some mm across as shown in [Figure 20](#).<sup>117</sup> The morphology of these failed regions in terms of the ratio of the diameter

**Figure 19** The temperature dependence of the time to spallation of the ceramic topcoat in various TBC systems in general commercial use.

**Figure 20** Decohesion of large sheets of the YSZ TBC on a coated 25 mm diameter specimen.<sup>117</sup>

of the area of decohesion to the thickness of the coating ( $\sim 20$ ) is consistent with buckling occurring during cooling (Section 1.27.4.2). This is supported by examination of cross-sections of partially failed coatings<sup>122</sup> and by extensive modeling.<sup>123</sup> Edge cracking can also, in principle, produce spallation of large areas of the coating<sup>123</sup> but this appears to be a much more variable event than buckling. It has not occurred, for example, in the specimen shown in Figure 20 but there are other cases of laboratory samples where coating failure at edges has occurred<sup>117</sup> but also accompanied by failure remote from these sites.<sup>124</sup>

As discussed in Section 1.27.4.2, catastrophic buckling will occur during cooling only when a delamination zone of critical radius has formed under the coating. Preexisting zones of this size are not present in the as-manufactured coating and must form during the high temperature exposure. The relatively slow growth of these subcritical defects determines the life of the TBC system and, understandably, there has been much interest in techniques which can assess the extent of this damage nondestructively. Studies of the use of impedance spectroscopy have been made<sup>125</sup> but a more developed technique to date is that of laser-activated luminescence of trace  $\text{Cr}^{3+}$  ions within alumina. Application of this to TBC systems has been pioneered by Clarke and coworkers.<sup>126–128</sup> A particularly powerful aspect of the technique is its ability to determine regions in which the alumina TGO within TBC systems has relatively low stress after cooling to room temperature. By laser scanning the specimen, it is

possible to construct a map showing the extent of these low-stress regions as a function of exposure time. A particularly satisfying example is shown in Figure 21<sup>129</sup> for a platinized BC system exposed to repeated thermal cycles from 1150 °C.

The darker regions in this figure are those of relatively low in-plane compressive stress compared with the lighter regions. The low-stress regions can be interpreted as damaged, involving cracks at either the TGO–BC interface or within the TGO itself. For this particular example, it is clear that the extent of the damaged regions increases markedly only after 190 h leading to spallation of some of the TBC topcoat after 225 h.

The attractions of using this nondestructive technique to evaluate the residual life of TBC systems *in situ* within turbines are considerable but there are cautionary factors. The first to note is that although an EB-PVD YSZ topcoat is transparent to the laser light there is lateral spread of the beam so that return signals are obtained from an area of  $\sim 20$ – $60\ \mu\text{m}$  diameter.<sup>128,129</sup> It follows that early-stage cracks, perhaps  $5\ \mu\text{m}$  long, will not readily be detected. This may be why there appears to be an extensive damage-free period in the example shown in Figure 21 whereas, in reality, small cracks may already have nucleated. For APS topcoats, the applicability of the technique is less clear since the lateral splat boundaries now form internal interfaces across the path of the impinging laser beam and significant attenuation of the return signal is likely.

The other important consideration is the location of the spallation interface. In practice, cracks can form within the topcoat near the TGO, at the TGO–topcoat interface, within the TGO, and at the TGO–BC interface. The luminescence technique relates damage to a decrease in stress within the TGO and this will occur only if cracking occurs within the TGO itself or along its interface with the BC. Fracture damage occurring at the other locations will not be detected by the luminescence technique. For the example of the platinized BC shown in Figure 21, fracture damage did indeed develop both at the TGO–BC interface and within the TGO. The luminescence technique would detect this, subject to the limits on spatial resolution. There are many examples in the literature of crack formation in TBC systems and a perceived tendency for the spallation path to be at the TGO–BC interface in Pt-aluminide/EB-PVD YSZ systems. This is indeed frequently the case but it does not seem to be an intrinsic feature of this system, however, since fracture along the TGO–topcoat or within the topcoat

**Figure 21** Map showing the development of low-stress regions (dark areas) with increasing number of cycles, containing 1 h hold periods at 1150 °C, for a TBC system consisting of an EB-PVD YSZ topcoat and platinized BC. Note that a single specimen was examined sequentially but not the same area.<sup>129</sup>

has also been observed.<sup>117</sup> This cracking is often associated with BC protuberances, that is, with increased roughness of the BC. An example of the early stages of cracking within the topcoat of a (rough) Pt-aluminate/EB-PVD YSZ system is shown in [Figure 22](#).

By contrast, the perceived tendency with MCrAlY/APS YSZ systems is for the fracture path to lie mainly within the topcoat. Again, this is not an intrinsic property of the system but is associated with the generally rough BC surface. An example of multiple fracture sites, that is, within the topcoat, within the TGO and at the TGO–BC interface in such a system is shown in [Figure 23](#). Here, the principal

crack, marked A, is hundreds of microns long and lies at the base of the topcoat. It intersects sites, marked B, of porous nonprotective oxides resulting from CF. There is also a crack, marked C, along the TGO–BC interface which appears to be linked to an inclined shear crack traversing the thickness of the TGO. This is a similar morphology to that expected for wedge cracking ([Section 1.27.4.2](#)).

### 1.27.5.3 Strain Energy Considerations

The driving force for spallation within the TBC system is the release of the stored strain energy

**Figure 22** SEM image of a section through a TBC system consisting of a Pt-aluminide bond coat with an EBPVD YSZ top coat that has been held at 1200 °C for 3 h. Small cracks have developed, arrowed, at the flanks of BC protuberances. Courtesy of Dr. M.P. Taylor.

**Figure 23** Section through a TBC system consisting of an electroplated CoNiCrAlY BC and an APS topcoat after oxidation in air at 1100 °C for 600 h. Different cracking sites are indicated and described in the text. See text for discussion. Courtesy of Dr. M.P. Taylor.

within the respective layers. It is an analogous situation to the spallation of the alumina layer from a MCrAlY coating discussed in [Section 1.27.4.2](#). As in that case, [eqn. \[19\]](#) can be used as a first approach but it needs to be noted that this is a ‘thin-layer’ approximation which makes no allowance for any strain energy stored within the coating and alloy substrates. As pointed out earlier, it also assumes that negligible stress exists at the exposure temperature and that the strain energy derives only from thermal loading.

The stored energy within the topcoat will depend linearly on the in-plane Young’s modulus ([eqn. \[19\]](#)) but this parameter is not well defined, particularly for EB-PVD topcoats. Here the in-plane modulus will

vary through the coating thickness and is likely to reach its highest value at its base. Nevertheless, for purposes of illustration, consider a topcoat of thickness 200 μm with an average Young’s modulus of 50 GPa, which is representative of literature values. Using linear thermal expansion coefficients of  $12 \times 10^{-6} \text{ K}^{-1}$  for the topcoat and  $15 \times 10^{-6} \text{ K}^{-1}$  for the superalloy and 0.1 for the Poisson’s ratio of the topcoat within [eqn. \[19\]](#) yields a value for the stored strain energy within the topcoat of  $81 \text{ J m}^{-2}$  on cooling to 100 °C from 1100 °C. It is the release of this energy that will develop cracks at the TGO–topcoat interface or within the topcoat near the TGO. It should be noted that this strain energy may change with time as a result of sintering of the topcoat and an increase in its Young’s modulus<sup>130</sup> or it may decrease as a result of thinning due to chemical or physical erosion.<sup>131</sup>

The specific strain energy within the TGO will increase as the oxide thickens and, in principle, should be added to that within the topcoat to produce cracking either within the oxide layer or at the interface between the TGO and the coating. The strain energy within the TGO can be calculated from [eqn. \[19\]](#). For an oxide thickness of 4 μm, that is, corresponding to the failure line drawn in [Figure 19](#), and using similar parametric values as previously, gives a specific stored energy within the TGO of  $53 \text{ J m}^{-2}$ . The total energy available to produce fracture within the TGO or along the oxide–coating interface is then  $134 \text{ J m}^{-2}$  for the example used.

These values of specific strain energy should certainly be sufficient to produce cracking even with the dissipation of energy by creep anticipated for typical (MCrAlY) BCs – see, for example, [Section 1.27.4.2](#) and [Table 3](#). Interestingly, the stored energy within the topcoat is available to produce cracks within the TBC layer or at its interface with the TGO from the onset of exposure. The reason that cracking is deferred and that TBC systems survive beyond the first thermal cycle is that there must also develop a mechanism for producing cracking and releasing this energy. This is a product of the high temperature exposure and various suggested possibilities will be described briefly in the next section.

### 1.27.5.4 Formation of Subcritical Cracks

#### 1.27.5.4.1 Transformation strains

The removal of aluminum from the BC both by selective oxidation and interdiffusion will result in phase transformation and associated volume changes.

The most obvious of these, evident in **Figure 8(b)** for example, is the transformation from  $\beta$  to  $\gamma'$  phases. Tolpygo and Clarke<sup>132</sup> have estimated an associated volume contraction during this process of  $\sim 38\%$  and have suggested that this transformation strain could induce BC rumpling and decohesion. A difficulty with the calculation is that, in the vicinity of the TGO, the transformation occurs as a direct result of the removal and oxidation of aluminum. The volume change at this location should then also include the expansion arising from formation of alumina. When this is done,<sup>133</sup> the transformation (and concurrent oxidation), is found to produce a volume expansion, rather than contraction, which is of similar magnitude to that produced by direct oxidation of aluminum. Little effect of the  $\beta$  to  $\gamma'$  transformation on TGO adherence and mechanical stability of the BC surface should then be expected and this seems to be borne out by observations.<sup>134,135</sup> It can also be seen from **Figure 8(b)** that there is no marked indentation of the coating–oxide interface above the large  $\gamma'$  phase. It is worth noting, though, that at the inner surface of the BC where interdiffusion is occurring with the alloy substrate, the volume change associated with alumina formation should not be included in the calculation of total volume. The transformation may result in contraction strains in this case which could contribute to the cavity development sometimes found at these locations. It is not easy to calculate these transformation strains, however, since other, often poorly characterized, phases will form within the interdiffusion zone and the volume changes associated with these should also be taken into account.

Another transformation of interest is that of martensite formation of the  $\beta$  phase during cooling. This has been recognized for many years for  $\beta$ -NiAl<sup>136,137</sup> and has also recently been confirmed in  $\beta$ -(Ni, Pt)Al coatings.<sup>134,138,139</sup> Typical of martensitic transformations, a critical cooling rate is required but this seems remarkably low in this case where martensite has been found after air cooling<sup>138</sup> and even after furnace cooling.<sup>139</sup> The former, at least, is consistent with earlier observations on  $\beta$ -NiAl.<sup>140</sup> These recent results suggest that martensitic transformation of the  $\beta$ -(Ni, Pt)Al phase should be a common occurrence during cooling.

The formation of martensite will result in a volume change estimated at  $\sim -2\%$ , that is, a linear contraction of  $\sim 0.7\%$ .<sup>138,139</sup> Unlike the  $\beta \rightarrow \gamma'$  transformation discussed earlier, the expansion due to alumina formation will not mitigate this transformation strain and

out-of-plane tensile stresses may be produced across the TGO–BC interface at the transformation temperature of  $\sim 450\text{--}500^\circ\text{C}$ .<sup>139</sup> The magnitude of these is unclear since the strains may also be accommodated by void formation within the original  $\beta$  grain and some thermal or athermal relaxation may still be possible at this temperature. There is a strong circumstantial argument, however, that the transformation is not a significantly damaging event. If it were so, both Pt-aluminide and MCrAlY coatings would tend to fail before  $\beta$ -depletion had occurred. In practice, much of the life of MCrAlY coatings, for example, is spent with a  $\beta$ -depleted zone adjacent to the TGO layer. Platinized  $\gamma/\gamma'$  coatings, of course, never form the  $\beta$  phase.

#### 1.27.5.4.2 Mechanical instabilities

The alumina TGO layer is under compression during cooling and will also be so at temperature if growth stresses are compressive. The strain energy within the layer can be released and contribute to decohesion if the oxide layer can relax and extend to its stress-free dimensions. The linear relaxation strain per cooling transient will be no more than  $\sim 0.5\%$ , equivalent to an extension of  $0.1\text{ }\mu\text{m}$  over a  $20\text{ }\mu\text{m}$  distance. Large dimensional changes of the TGO layer over these small lengths would then require multiple thermal cycles.

One suggested mechanism is that of ratcheting.<sup>135,141</sup> The initiating event, in this case, is the formation of small cracks within the TBC above preexisting undulations of the BC, essentially as shown arrowed in **Figure 22**. These cracks remove mechanical constraint from the underlying TGO which, as discussed earlier, may be under a compressive growth stress at the oxidation temperature but will certainly experience large in-plane compressive stresses during cooling. Within the model, it is envisaged that, with increasing number of cycles, these stresses can drive the oxide layer as an indent into the BC and, in doing so, enlarge the crack at the base of the topcoat. The model seems feasible, in principle, and experimental support has been provided<sup>135</sup> although the incidence of failure by this route does not seem widespread. It is often observed, for example, that the main fracture site in TBC systems with such diffusion BCs is at the TGO–BC interface<sup>51,52,128</sup> rather than within the TBC topcoat. A key aspect is that there needs to be either a certain roughness to the BC surface so that cracks such as those in **Figure 22** can form or there needs to be a defect at the base of the topcoat which offers no

constraint to the downward migration of the TGO. The issue of surface roughness will be addressed in later sections.

There will probably exist a window of BC strengths within which the ratcheting process could occur. It is not possible to quantify this because modeling the progressive indentation is difficult and has tended to assume<sup>135,141</sup> that the BC deforms by athermal plasticity characterized by yield behavior. In fact, creep processes will dominate,<sup>142,143</sup> even during cooling.<sup>133</sup> Low creep strength is necessary to move the BC away from the indenting oxide but this deformation occurs at constant volume. There must, thus, also be an upwelling of the displaced matter against the TBC topcoat adjacent to the indent. In this case, the creep strength of the BC must be high enough to displace the topcoat upward and allow continued penetration of the indenting oxide layer into the BC. These two contradictory requirements of the BC creep strength may be satisfied only within a limited temperature and composition range.

Another interesting mechanical instability is rumpling. This has been recognized for some years and has been shown to occur in aluminized and Pt-aluminized coatings under thermal cycling conditions<sup>132,144,145</sup> but in the absence of a topcoat. It is manifested by a roughening of the specimen surface and is clearly associated with thermal cycling because isothermally-tested specimens do not show the phenomenon.<sup>144</sup> The basic underlying reasons for the surface instability are well understood<sup>146,147</sup> and are broadly the same as discussed above for the ratcheting process. In both cases, deformation of the coating permits the compressively stressed TGO to increase its length and, thereby, relax its strain energy. As pointed out earlier, this increase in length per temperature transient is small,  $\sim 0.5\%$ , and repeated thermal cycles are needed to produce readily observable deformation.

The rumpling process has been implicated<sup>147</sup> in failure of the TBC system because the instability would develop significant out-of-plane stresses in the vicinity of the TGO with associated crack initiation. Modeling of the process again assumes plastic yielding rather than creep behavior and, although the presence of the topcoat is considered, no mechanical constraint is attributed to it. This constraint will be present in real cases and, for the reasons given above when discussing ratcheting, is likely to limit the applicability of the process in TBC systems. Again, exceptions will arise when defects exist in the topcoat such that, locally, mechanical constraint is absent and upward displacement of the TGO and BC becomes feasible.

#### 1.27.5.4.3 Roughness of the BC surface

It has been known for some time that the roughness of the BC surface will have a significant influence on the development of stresses in the TBC system during cooling.<sup>148,149</sup> Various attempts have been made to evaluate these using FE methods<sup>113,130,133,150–153</sup> which incorporate materials' behavior of varying degrees of relevance. Most recently, it has also become clear that out-of-plane tensile stresses can also develop at the oxidation temperature as a consequence of the volume increase on oxide formation.<sup>112,113</sup>

The development of these numerical models has to some extent mirrored the expansion in computing power. Thus, initial approaches tended to assume entirely elastic behavior of the respective layers but, importantly, creep behavior has been subsequently incorporated and recognition made that the TGO thickens during exposure. The most recent models<sup>113,130,133</sup> incorporate creep of both BC and TGO, allow for growth of the latter together with the associated volume change at temperature during the computation. In addition, they permit densification of the YSZ topcoat, again during the simulated exposure time, and consider a variation in BC surface roughness. Some predicted results for two different BC-roughness geometries are shown in **Figure 24**.<sup>133</sup>

As described in the caption, the stress contours of **Figure 24** apply to the situation at the test temperature of  $1100^\circ\text{C}$ . For the case examined, the total thickness of the alumina TGO had increased to  $3.3\ \mu\text{m}$  during the simulated 100 h isothermal exposure at this temperature. The parameters  $b$  and  $a$  are the amplitude and half-wavelength, respectively, of the surface undulations shown in **Figure 24**. For the rougher surface, **Figure 24(a)**, out-of-plane tensile stresses of  $\sim 150\ \text{MPa}$ , have developed within the topcoat along the flank of the BC protuberance. For the less-rough surface, however (**Figure 24(b)**), these stresses are absent, showing the strong sensitivity of isothermal stress development to BC surface roughness. In both cases, tensile stresses also develop in the valleys of the undulations.

The out-of-plane tensile stresses on the flanks of the BC protuberance arise from continuity strains<sup>112</sup> which are required if the topcoat is to remain uncracked. Their origins can be understood by recognizing that the outward displacement due to the formation of the TGO is normal to the BC interface and, so, changes direction around the protuberance shown in **Figure 24**. The out-of-plane component, the  $x_{22}$  direction, of this displacement also varies around the protuberance and reaches a

**Figure 24** FE predictions<sup>133</sup> of the  $\sigma_{22}$  stress contours at 1100 °C after 100 h oxidation at the same temperature for an EB-PVD YSZ TBC system containing a Pt-aluminide BC. Creep of the BC and TGO, sintering of the topcoat and outward strains due to TGO growth are considered in the stress analysis. The BC creep properties used were those of Taylor *et al.*,<sup>143</sup> The arrowed locations mark the general sites of high stress at the flank (a) and valley (b) regions.

minimum on its flank. To maintain continuity of the topcoat, tensile stresses must then develop to strain the topcoat in these locations to account for the out-of-plane deficit in the displacements resulting from oxide growth.

The effect, on the  $\sigma_{22}$  stress distribution, of cooling the specimen to 25 °C after the isothermal exposure for 100 h at 1100 °C is shown in **Figure 25**, again for the two BC surface roughnesses.<sup>133</sup> The out-of-plane flank stresses in the rougher specimen, **Figure 25(a)**, are largely unaffected by this transient and no new stress is developed in these locations in the less-rough specimen, **Figure 25(b)**. There is a large increase, however, in the tensile stress developed in the topcoat in the valley regions and across the TBC–TGO interface. For the rougher surface, this is ~700 MPa but is appreciably smaller (~200 MPa) for the smoother surface. Significant tensile stresses are also developed at the TGO–BC interface during cooling as a result of differential contraction strains between oxide and coating (see Ref. [37] for a general review of such issues). Broadly, the same behavior has also been found with MCrAlY BCs where, again, appropriate creep and oxide growth kinetics were incorporated into the FE modeling.<sup>113</sup>

These regions of high stress correspond to locations where cracks form in TBC systems. Examples of those found at flank and valley locations are arrowed in **Figure 22** and may well have formed at temperature. Crack initiation, presumably during cooling, has also been reported<sup>113</sup> at the TGO–BC interface at the peak of the BC protuberances. These nucleation processes will occur, however, only with relatively rough BCs. Cracking events should be less easy and TBC lifetimes would be expected to be longer with flatter BC surfaces. This has been clearly demonstrated recently by Yanar *et al.*<sup>117</sup> who found an approximate factor 10 increase in the lifetime of a NiCoCrAlY/EB-PVD YSZ system by hand polishing the BC prior to deposition of the topcoat.

#### 1.27.5.4.4 Chemical failure

A discussion of CF processes in relation to aluminum depletion and the endurance of overlay coatings has been given earlier in **Section 1.27.4.3.2**. Identical concepts apply to BCs in TBC systems but, in this case, spallation of the YSZ topcoat may be induced prior to complete CF of the BC.<sup>105</sup> This can arise because CF will result in the fast growth of nonalumina, break-away-type oxides which will produce upward displacements of the topcoat. This is an oxide-jacking

**Figure 25** FE contour plots of the  $\sigma_{22}$  stress for the same specimen as shown in Figure 24 but after cooling to 25 °C after exposure at 1100 °C for 100 h.<sup>133</sup> The arrows indicate the general areas in which out-of-plane stresses had developed prior to cooling.

process which will result in the development of out-of-plane tensile stresses within the topcoat when the CF sites are discrete (Figure 26). Possible localized sites for enhanced aluminum depletion and the early initiation of CF are diffusion cells (splats) within sprayed MCrAlY BCs,<sup>105</sup> protuberances (roughness) at the BC surface,<sup>109,111,153</sup> and locally thin cross-sections.

The jacking associated with the formation of the mound of fast-growing (Ni, Cr)-rich breakaway oxides, shown schematically in Figure 26, will tend to nucleate and propagate delamination cracks within the topcoat near the TGO. This process will occur at the oxidation temperature and will not need thermal cycles to produce this damage. It is likely that this type of process was responsible for the long crack (marked A) in the cross-section shown in Figure 23. This particular specimen had been exposed isothermally until the final cooling transient and several discrete regions of breakaway oxides (marked B), associated, in this case, with BC protuberances, had formed.

#### 1.27.5.5 Surface Roughness: A Common Factor?

A number of the degradation mechanisms described in Section 1.27.5.4 have been observed experimentally and, consequently, have validity. The

**Figure 26** A schematic diagram showing how the growth of fast-growing 'breakaway' oxides resulting from CF will generate out-of-plane tensile stresses within the topcoat.

importance of others (phase transformation strains, rumpling) to TBC failure is less clear and awaits more robust experimental support. Of those mechanisms which have been shown to nucleate and propagate subcritical cracks, some are either aided by or, indeed, require BC surface roughness (e.g., CF, out-of-plane tensile stress development at temperature or during cooling, ratcheting) and others (wedging) are likely to operate only on relatively flat interfaces. The

experiments of Yanar *et al.*,<sup>117</sup> in particular, show very well that decreasing the surface roughness of a MCrAlY BC can increase the lifetime of a TBC system by an order of magnitude. The improved behavior was similar in their experiments to the behavior of a Pt-aluminide BC which had similarly flat BC surfaces. As can be appreciated from Figure 22, however, flat Pt-aluminide BCs with EB-PVD topcoats need not always be the case and will depend on the extent of grit blasting performed by the manufacturer. The factor 10 improvement in lifetimes found by Yanar *et al.* is of the same order of magnitude found in the compilation of published lifetime results from commercial systems shown in Figure 19. It is certainly tempting to suggest that much of this scatter in lifetimes can be attributed to an uncontrolled variation in the surface roughness of the BCs. There will be other sources of scatter, inevitably included within these various tests, but the first-order importance of BC surface roughness to the scatter at any given temperature can be taken as a working hypothesis.<sup>113</sup>

The dependence of the various delamination mechanisms on surface roughness are only now being assessed quantitatively using realistic numerical models which, as described in earlier sections, allow for creep processes and the volume expansion due to oxide formation. Work in this area is incomplete but some rather qualitative trend lines are

shown schematically in Figure 27 which relates TBC lifetimes to the BC surface roughness.

Relatively flat surfaces (low values of  $b/a$ ) provide the longest lifetimes since opportunities for crack nucleation caused by continuity strains and CF will be limited. Studies of failure processes in such ideal structures are limited although in localized areas of otherwise rough BCs, wedge-type cracks have been found (Figure 23 but see also Section 1.27.4.2). The red line, representing continuity cracking in Figure 27, shows a decrease in lifetimes as BC roughness increases. It refers to the development of subcritical cracks at the flanks of BC protuberances at temperature, possible ratcheting nucleation, and the nucleation of cracks at the TGO/BC interface during cooling. The stresses produced increase with oxide thickness and, so, time at temperature is an important factor. They will also increase with the roughness factor  $b/a$  (Section 1.27.5.4.3)<sup>113</sup> and it is expected that TBC lifetimes will decrease as this increases. For large values of  $b/a$ , aluminum depletion within BC protuberances will be enhanced (e.g., Figure 18) and CF with the formation of breakaway-type oxides will take place. These will increase the stresses produced within the TBC layer at temperature and failure will occur earlier than in the absence of breakaway. This trend is shown as the downward-sloping blue line in Figure 27. Again, time at temperature will also be an

**Figure 27** A schematic map showing how variously proposed mechanisms for the nucleation and growth of subcritical cracks may depend on the surface roughness of the BC. The colored lines show possible dependences of continuity cracking and CF on roughness.

important parameter since the depletion of aluminum will be directly related to this.

As a final note of caution, it should be emphasized that the discussion in this section relates to typical laboratory experience in which the test specimens have relatively simple shapes. The map of Figure 27 then provides a mechanistic framework for these conditions but the concepts are also expected to be valid for service conditions although some modification might well be required. There may be thin regions, for example, within the complex geometry of actual components in which the local total aluminum reservoir is insufficient to maintain a protective TGO. Bulk depletion and breakaway oxidation could then occur prematurely and failure by this route might then be only weakly dependent on the surface roughness of the BC. In another example, local regions of components may be designed with a high radius of convex curvature and could develop significant out-of-plane tensile strains during cooling. These would contribute to the continuity strains developed solely from the surface roughness of the BC. As discussed earlier, similar issues would apply for the case of imposed service strains.

### 2.01.1 Thermodynamics

The corrosion reaction is an electrochemical cell. Like other electrochemical cells such as batteries, corrosion requires at least one anodic and one cathodic half reaction, where anodic reactions generate electrons and cathodic reactions consume electrons. In closed electrochemical cells, charge is conserved; there is no net generation or consumption of electrons.

For a generic metal  $M$  dissolving in an acidic solution, the dominant half reactions might be

Each half reaction will be in equilibrium (where the rates in the forward and reverse directions are equal) at a reversible potential. For half reactions in which all reactants and products are in their standard state, the reversible potential is given by the standard potential,  $E^\circ$ , which can be calculated from the difference in standard free energy of formation of the products and reactants,  $\Delta G^\circ$ , the number of electrons transferred in the half reaction,  $n$ , and Faraday's constant,  $F$ , according to

$$E^\circ = -\Delta G^\circ / nF \quad [3]$$

Reversible and standard potentials of any half reaction versus a suitable reference electrode are given. It is customary to use the standard hydrogen electrode (SHE) shown in eqn [2] as a universal reference when listing the potential of a half-cell. Under standard state conditions, the activity of the protons is unity,  $a_{H^+} = 1$ , and the partial pressure of hydrogen gas is one bar,  $P_{H_2} = 1$  bar (1 bar = 0.987 atm). The potential of the

SHE is arbitrarily set at zero,  $E_{SHE}^\circ \equiv 0$ . Correspondingly, this means that the free energy of protons in solution at unit activity is arbitrarily set to 0 as a reference point, which is required for any free energy scale.

In the more general case where species are not present in their standard state concentrations, the reversible potential at equilibrium for a half reaction,  $E^{rev}$ , is given by the Nernst equation

$$E^{rev} = E^\circ + \frac{RT}{nF} \ln \left\{ \frac{\Pi(a_{ox})^j}{\Pi(a_{red})^k} \right\} \quad [4]$$

where  $R$  is the gas constant,  $T$  is temperature, and  $\Pi(a_{ox})^j$  and  $\Pi(a_{red})^k$  are the products of the activities of the oxidized and reduced species respectively, raised to a power equal to their stoichiometric coefficients in the half reaction equations. For dilute solutions, the activity coefficient is approximately equal to one. Therefore

$$a_A = \gamma_A c_A \approx c_A = [A] \quad [5]$$

where  $\gamma_A$  is the activity coefficient of species  $A$ , and  $c_A$  and  $[A]$  represent the concentration of species  $A$  in units of moles per liter. It should be noted that equating activity to concentration for dilute concentrations is a statement of Henry's law, which utilizes a hypothetical standard state of 1 mol  $l^{-1}$ . The Henrian activity is different than that obtained from Raoult's Law, which states that activity equals mole fraction (activity coefficient equals 1) when mole fraction is close to unity. Raoultian activity is used commonly in electrochemistry for gases and solvents. Thus, for the general half reaction

The Nernst equation is

$$E^{\text{rev}} = E^{\circ} + \left(\frac{RT}{nF}\right) \ln \left(\frac{[A]^a[B]^b}{[C]^c[D]^d}\right) \quad [7]$$

And at room temperature

$$E^{\text{rev}} = E^{\circ} + \left(\frac{0.059}{n}\right) \log \left(\frac{[A]^a[B]^b}{[C]^c[D]^d}\right)$$

The reversible potentials calculated from Nernst equations are important in corrosion, because half reactions will proceed in the net anodic (oxidizing) direction only at potentials more noble than the reversible potential. Similarly, cathodic (reducing) reactions will occur only at potentials less anodic than the reversible potential. Therefore, an analysis of the reversible potentials for two reactions provides insight into the thermodynamic likelihood for an electrochemical cell to proceed in the direction required for corrosion to occur: the reversible potential for the cathodic reaction must be higher than that for the anodic corrosion reaction.

### 2.01.2 Kinetics

Since electrochemical half reactions either generate or consume electrons, their rates can be assessed and measured as currents, or current densities when normalized to the area. As mentioned, an electrochemical half reaction will proceed in the net anodic or cathodic direction at potentials above or below the reversible potential respectively. At the reversible potential, the reaction proceeds in both directions

at the same rate, which when converted to the units of current density is called the exchange current density,  $i_0$ .

Electrochemical kinetics describe the rate of an electrochemical reaction as a function of the potential relative to the reversible potential or a reference electrode. In general, the rate of an electrochemical half reaction increases as the potential difference from the reversible potential increases. At a large enough potential difference from the reversible potential, the Tafel equation describes this relationship when the rate is limited by the transfer of charge across the interface:

$$E - E^{\text{rev}} = b \log(i/i_0) \quad [8]$$

where  $b$  is the Tafel slope. On a plot of  $E$  versus  $\log |i|$ , called an Evans diagram, this expression is a straight line with the slope of  $b$ . In Figure 1, the expression is plotted as  $\log |i|$  versus  $E$  and the slope is  $1/b$ :

$$\log i = \log i_0 + \frac{E - E^{\text{rev}}}{b} \quad [9]$$

As shown in Figure 1, the hydrogen evolution reaction, eqn [2], goes in the cathodic direction at potentials below the reversible potential for that reaction, which is given by the Nernst equation. The metal dissolution reaction goes in the anodic direction at potentials above the reversible potential for that reaction.

Many metals will dissolve by uniform corrosion when immersed in an acidic solution. In an acid, the primary cathodic reaction is often the hydrogen evolution reaction, and metal dissolution may be written as eqn [1]. Both reactions will occur on

**Figure 1** Schematic Evans diagram for corroding active metal in an acid. Reproduced from Frankel, G. S.; Landolt, D. In *Corrosion and Oxide Films*, Stratmann, M., Frankel, G. S., Eds.; 2003; p. 38, with permission from Wiley-VCH Verlag GmbH & Co. KGaA.

the same surface at essentially the same potential. This potential is called a ‘mixed potential,’ because it is between the reversible potential of the two reactions. It is also called the open circuit potential (OCP) or for a corroding metal, the corrosion potential,  $E_{\text{corr}}$ .

As shown in **Figure 1**,  $E_{\text{corr}}$  is the potential at which the anodic and cathodic current densities are equal, which is required for charge neutrality. For the more general case where there might be more than one anodic or cathodic reaction,  $E_{\text{corr}}$  at any point in time is the potential where the following is obeyed:

$$\sum i_a = \sum i_c \quad [10]$$

For uniform corrosion to occur, the anodic reaction must not be localized at specific spots on the surface of a sample. Instead, the anodic reaction must occur at multiple sites across the surface and continually move to new sites, thereby evenly removing material across the surface over time. Similarly, the cathodic reaction must not be localized. When these reactions remain at fixed locations, the attack is nonuniform, resulting in a localized form of attack such as pitting, crevice, or intergranular corrosion.

### 2.01.3 Passivity

Another form of nominally uniform attack involves a passive metal surface rather than the active dissolution described in the previous section. Passivity describes the relatively low rate of corrosion exhibited by metals covered by a thin oxide or hydroxide film, the passive film. Passive films are thermodynamically stable at high potentials for many metals. For example, the Nernst equation can be calculated for a reaction in which a metal oxide is formed from a metal in an aqueous solution:

$$E^{\text{rev}} = E^\circ - 0.059\text{pH} \quad [12]$$

where  $E^\circ = -(nG_{\text{H}_2\text{O}}^\circ - G_{\text{MO}_n}^\circ)/nF$  following **eqn [3]**. As indicated before, at potentials above this reversible potential, reaction [11] would tend to go in the anodic direction, from right to left or the opposite direction of what is written in **eqn [11]**, resulting in the formation of an oxide film. For many metals, this potential is below the potential for hydrogen evolution associated with proton or water reduction, and therefore, the passivation reaction will proceed spontaneously in aqueous solutions.

Passive films form spontaneously in the majority of practical environments on stainless steels, and

alloys of Al, Ni, and Ti. Fe spontaneously passivates at high pH or at high potentials. W, in contrast, spontaneously passivates at low pH. For many metals, including Al, Cu, and Zn, the passive oxide film is stable only in the mid-pH region. These metals are described as being amphoteric in nature.

Stainless steels are iron-based alloys with good corrosion resistance owing to the formation of a Cr-rich passive film. When Fe is alloyed with >13% Cr, such a protective passive film can form, thereby achieving the good corrosion protection associated with Cr while maintaining the mechanical properties of steel. Common grades of stainless steel contain 16–20% Cr, as well as other elements such as Ni and Mo.

Spontaneously formed passive films typically have a thickness of 2–4 nm, although they tend to thicken as the potential is increased. The protectiveness of passive films usually increases with potential, and the application of a high potential often improves the corrosion resistance by thickening the passive film. This is the basis for anodization, which is commonly performed on Al to thicken the aluminum oxide layer. At room temperature, the thickness increases by about  $1.2 \text{ nm V}^{-1}$ . Iron and nickel oxides are semi-conducting so that they support the oxygen evolution reaction at potentials above the reversible potential for that reaction, and therefore cannot be anodized to high potentials. Cr-rich passive films that form on Cr and Cr-containing alloys such as stainless steel dissolve at high potentials forming the soluble chromate ion (a process known as transpassive corrosion), and thus also cannot be anodized.

It should be noted that almost all metals and alloys that can be protected by a spontaneously formed passive film are susceptible to accelerated localized corrosion such as pitting or crevice corrosion as the result of localized breakdown of the otherwise protective passive film. Such breakdown requires the presence of an aggressive species, such as chloride ions, and is accelerated for many passive metals by the presence of high chloride concentration, high temperature, and high potentials.

### 2.01.4 Uniform Corrosion in Practice

Metals and alloys can corrode uniformly in one of three states:

- Active

In this case, the metal is in direct contact with the environment, the rate of corrosion being controlled by the kinetics of the anodic and cathodic

reactions, with a contribution (usually small except in pure waters) of solution resistance due to the separation between the instantaneous anodic and cathodic sites on the metal surface. It is normally only practicable to use alloys in this state if the rate of hydrogen evolution is low, which effectively limits alloy systems that can be used in this state in practice to those based on metals with an equilibrium potential that is not too far below that for hydrogen at the relevant pH (such as copper, nickel, and iron), or on metals that have a very low exchange current density for hydrogen evolution (such as lead and zinc). In aerated environments, it is common for the rate of corrosion to be controlled by the transport of oxygen to the metal surface, which leads to a typical uniform corrosion rate in air-saturated solutions such as seawater of  $0.1\text{--}1.0\text{ mm year}^{-1}$ , depending on the flow conditions. In stagnant liquids, soils and similar situations where the flow is restricted, when the surface is covered by a corrosion product film or when the solution has a low conductivity, such as many fresh waters, the corrosion rate will be lower.

- Immune

In this case the metal is the thermodynamically stable state and corrosion cannot occur at a significant rate (in an environment that is completely free of ions of the metal, there will be a very low corrosion rate as the metal oxidizes to a sufficient extent to achieve the metal ion concentration that is in equilibrium with the metal). In the presence of complexants or species that produce stable salts, the metal ion concentration may be maintained below the value that is in equilibrium with the metal, allowing corrosion to occur. Thus, in cyanide leaching of gold ores, gold ions are complexed by cyanide, allowing continuing corrosion of particles of metallic gold, with oxygen reduction as the cathodic reaction. In this condition, the metal is effectively corroding in the active state, although the kinetics will tend to be rather more complex.

- Passive

In the case of passive metals, the corrosion rate is controlled by the properties of the passive film. This is usually an oxide or hydroxide, although passivation by salt films is also possible. The kinetics of passive corrosion have been studied in considerable detail in recent years, largely because of the requirements of nuclear waste disposal, for which some approaches depend on the corrosion performance of passive alloys over many thousands of years (see **Chapter 2.39, Predictive Modeling**

**of Corrosion** for a detailed discussion of this work). Other applications where the rate of passive corrosion is important are in the primary circuit of water-cooled nuclear reactors, where the release of radioactive transmutation products from the metals of construction of the reactor leads to significant safety hazards, and in biomedical applications where the release of metal ions (such as nickel and chromium) can lead to allergic or toxic effects on neighboring tissue. Otherwise, the rate of passive corrosion is usually not significant, and the various forms of localized corrosion tend to present much more serious problems for passive alloys.

### 2.01.5 Uniform Corrosion of Iron

Unprotected iron will corrode and form rust in many environments. Lorenz and Heusler have provided a good summary of their work and others' on the mechanism of iron corrosion.<sup>1</sup> The reactions commonly used to describe this process in an aerated environment are

where the final iron oxide product, red rust, is usually a hydrated form of  $\text{Fe}_2\text{O}_3$  (usually assigned the formula  $\text{FeO}(\text{OH})$ ). However, it seems unlikely that solid  $\text{Fe}(\text{OH})_2$  is formed, as this would be expected to lead to a form of passivation, with an underlayer of  $\text{Fe}(\text{OH})_2$  covered by  $\text{Fe}_2\text{O}_3$ , and it is more likely that the oxidation of ferrous species to ferric occurs in solution, leading to precipitation of rust in solution away from the surface of the metal, resulting in the nonprotective corrosion product film that everyone is familiar with. In a deaerated aqueous environment (in the absence of oxygen), the cathodic reaction is hydrogen evolution via proton (eqn [2]) or water reduction and the ferric product will not form. The rate of reaction in this case is low in neutral or alkaline environments.

The mechanism of ferrous ion formation has been shown to be more complicated than eqn [13] as it involves multiple single electron transfer steps and depends on the pH of the environment:

The second charge transfer step (reaction [18]) is the rate-determining step, and in consequence, the rate of the overall reaction depends on the concentration of FeOH on the iron surface, and hence (by virtue of the equilibrium of reaction [17]) on the pH. Thus, in deaerated environments, the anodic and cathodic reaction kinetics both depend on pH; somewhat counter-intuitively, the rate of the anodic reaction at a constant potential decreases as the solution becomes more acidic (i.e., as the pH decreases), but this is countered in practice by the increase in the rate of the cathodic hydrogen evolution reaction due to the increased hydrogen ion concentration, which leads to an increase in the corrosion potential.

At high pH, iron spontaneously passivates as described earlier, forming a thin oxide layer. In neutral or acidic environments, passivity on Fe is only achieved by the application of a sufficiently high potential. If the potential is scanned, the polarization curve will exhibit an active-passive transition. In the active region, the current can be extremely high, approaching  $1 \text{ A cm}^{-2}$  (corresponding to a corrosion rate in the region of  $1 \text{ mm h}^{-1}$ ). In acidic solutions, a limiting current associated with mass-transport limited dissolution in the presence of a salt film on the surface can be observed over a range of potential. However, after the active-passive transition, the current density might drop by 4 orders of magnitude as a result of the formation of a thin passive film. On iron, the passive film has been found to be a bilayer, with an inner layer of  $\text{Fe}_3\text{O}_4$  and an outer layer of  $\gamma\text{-Fe}_2\text{O}_3$ .

Alloying of iron with carbon and other elements such as Mn and Si to make steel generally has a small influence on the corrosion rate, although sulfide inclusions (typically MnS) act as local sources of sulfide and other species that accelerate corrosion locally. However, alloying elements such as Cu, Cr, P, and Ni added in small quantities to create low-alloy steels can result in considerable improvement in corrosion resistance. One class of low-alloy steels specifically designed for improved atmospheric corrosion resistance is referred to as weathering steels.<sup>2</sup> The rust layer on weathering steels is more compact and protective than that formed on plain carbon steel, although not as thin and protective as the passive film formed on stainless steels having Cr content  $>13\%$ . The protectiveness of this compact thick film formed on weathering steels is improved by periodic drying, and hence, their primary use is in atmospheric exposure rather than immersed or buried conditions. However, under many atmospheric conditions, the oxide layer on

weathering steels provides sufficient protection even without painting, which is a huge advantage as the maintenance costs associated with repainting degraded structures can be eliminated.

## 2.01.6 Uniform Corrosion of Copper

Copper is a noble metal in that its reversible potential is higher than that for the hydrogen evolution reaction. Therefore, Cu is thermodynamically immune to corrosion in deaerated noncomplexing environments. This is the reason why, at the time of this writing, many countries are considering long-term disposal of high-level radioactive waste in Cu canisters that would be located in the anoxic (oxygen-free) saturated zone (below the water table) of a geologic formation. However, complexation of copper ions by, for instance, chloride or ammonia, or the presence of species, such as sulfide, that form copper salts that are more stable than the oxide, can decrease the reversible potential for Cu dissolution to the extent that it is below that of hydrogen evolution, rendering the Cu susceptible to corrosion even in anoxic environments.<sup>3</sup> Furthermore, Cu will corrode in the presence of oxygen and other oxidizing agents.

Cu is widely used in water distribution piping, both for hot and cold water. Cu water piping will occasionally fail by pitting corrosion. This form of attack is not well understood<sup>4</sup> (there appear to be several different mechanisms of pitting, at least some of which are microbially induced), and usually confined to certain districts or groups of houses. The concentrations of sulfate, chloride, hydroxide, carbonate, and bicarbonate ions can influence Cu pitting susceptibility.<sup>5</sup>

In aerated solutions, the surface of Cu is typically covered with a film of  $\text{CuO}$ , which provides marginal protection. In atmospheric conditions, Cu eventually develops a protective patina; in most atmospheres (where there is significant  $\text{SO}_2$  present as a result of pollution) this has the structure, composition, and characteristic green color of the mineral bronchite,  $\text{Cu}_4(\text{SO}_4)(\text{OH})_6$ .<sup>6,7</sup> The patina can also contain carbonate, or by the seashore, chloride.<sup>8</sup>

The corrosion rate of Cu in the atmosphere has been found to depend on the conditions existing during the initial period of the exposure. When the initial exposure was in the winter, the rate of corrosion over a period of years was greater than when the initial exposure was in the summer, indicating that the nature of the initial surface oxide film plays a critical role in the subsequent development of that film.

Cu is often alloyed for improved mechanical properties. Brasses and Al bronzes are susceptible to dealloying attack whereby the less noble alloying element is dissolved preferentially, leaving a porous structure with little mechanical strength. Dezincification is the most common form of dealloying, caused by the preferential dissolution of Zn from brass. A small addition of As to the alloy, only about 0.04%, will reduce the susceptibility to dezincification; additions of Sn, Sb, or P are also effective.<sup>9</sup>

### 2.01.7 Uniform Corrosion of Zinc

Zn is an active metal with good corrosion resistance in the atmosphere and in natural waters owing to the formation of a protective oxide or hydroxide surface film. This combination of low corrosion potential and low self corrosion rate makes it an ideal sacrificial anode for steel. Zn and Zn alloys are widely used as corrosion protective coatings on steel, often in combination with

paint overcoats. Most steel automotive body panels nowadays are galvanized prior to coating.

The pH of the environment has a large effect on the corrosion rate of Zn as Zn is amphoteric, corroding rapidly in low- and high-pH environments, but slowly in the pH range from about 6 to 12. As a result, the lifetime of galvanized layers is decreased in polluted locations where the mist and dew are acidic.

### 2.02.1 Introduction

This article was first published in the 3rd edition; it is reprinted here in its entirety with only minor typographic corrections and a few editorial comments incorporated as footnotes.

Passivity is a state of low corrosion rate brought about under a high anodic driving force, or potential, by the presence of an interfacial solid film, usually an oxide. The phenomenon of passivity has been defined in a number of ways,<sup>1,2</sup> most of which are similar in meaning. Although from the more literal sense of the word, passivity could include metals immune from corrosion (such as gold in water); in the parlance of corrosion science, this is specifically excluded. Passive metals are thermodynamically unstable<sup>3</sup>: they possess a kinetic stability, which is engendered by a solid interfacial film, without which corrosion would occur. The oxide film, formed anodically through a mechanism very similar to that of the corrosion process, stifles the rate of further oxidation (corrosion and further passivation) by forming a barrier between the metal surface and its environment. So, many metallic structures and components depend on the state of passivity for their stability. From an engineering point of view, the phenomenon of passivity is a remarkable one due to its requirement of the extremely thin film to procure passivity.

The typical passivating oxide film on many metals is only 1–10 nm in thickness and is produced by the oxidation of the surface to a depth measured in monolayers of atoms. Without the passivating oxide film, many metallic structures would corrode at a very fast rate, phenomenological evidence for this being provided by the very fast rates at which localized corrosion (such as pitting corrosion or stress-corrosion cracking) can propagate when passivity is disrupted, and regeneration of the passivating oxide film cannot take place. This thin oxide film is the stabilizing barrier which separates the potentially active metal from the environment, for structures smaller than a hypodermic needle and larger than an aircraft. Not surprisingly, passivity and passivation have been examined extensively in the past for many decades using a large range of techniques; despite the great deal of information and knowledge that has thereby been generated, there are many questions that remain to be answered before a complete understanding of the subject is achieved.\* For example, since the advent of stainless steel, it has been realized that this important class of material owes its stainlessness to the surface oxide film, and even now, despite the large amount of research, using a wide range of *in situ* and *ex situ* techniques, the exact nature of this oxide film remains to be resolved. Passivity of iron has long been recognized<sup>6–8</sup>; the modern theories relating to the passivating oxide film are primarily due to Evans.<sup>9–12</sup>

Passivity of a metal lies in contrast to its activity, in which the metal corrodes freely under an anodic driving force. The passive state is well illustrated by reference to a classical polarization curve prepared potentiostatically or potentiodynamically (Figure 1). As the potential is raised (in the anodic or positive sense) above the equilibrium potential between the metal and its dissolved ions, the driving force toward oxidation and the rate of dissolution increase; in the classical case, it represents an exponential rise of current with potential according to the Tafel equation.<sup>13</sup> When the potential is high enough, a dramatic reduction in the dissolution rate occurs, and the rate of dissolution remains low with further increase in potential. The latter state is the state of passivity and the minimum potential at which the low oxidation

**Figure 1** Schematic anodic polarization curve for a metal. Region AB describes active dissolution of the metal. BC is the active–passive transition, with passivation commencing at B. Passivation is complete only at potentials higher than C. The metal is passive over the range CD.

rate exists is the passivation potential. It is a feature of the passive state that the oxidation rate is independent of potential, or nearly so.<sup>14</sup> This feature does not define the state of passivity uniquely, as the diffusion-controlled dissolution reactions are also independent of potential, and passivity is not due to dissolution under diffusion control. Some surface films too, while displaying all the qualitative properties of passivity with respect to the polarization curve, allow a high corrosion current to pass, and cannot be regarded as passivating. An extreme example of this is the phenomenon of electropolishing, in which the rate of dissolution is controlled by the migration of ions through a viscous salt film layer, the rate is independent of potential, and the current density is high.<sup>14–17</sup> It is a primary requirement of passivity that the oxidation rate is small and it depends entirely on the application. The state of passivity is never perfect, and a passive metal always corrodes at a finite rate, albeit that this rate may be very low. The surface film forms a barrier between the metal and its environment, which retards further oxidation. Raising the potential in the passive state, while increasing the driving force toward oxidation, serves to thicken the surface oxide film, thereby increasing the barrier for further oxidation. It is this increase in the barrier film thickness with increase in potential that generates the potential independence of the oxidation rate as long as the metal remains passive. This phenomenon is used in high-voltage anodizing of some metals, in which highly resistive oxide films can be grown to a thickness of several hundred nanometers at high voltages.

\*Editor's note: This article embodies the state of the subject in about 1992. The subject has changed relatively little since then and most of the content is consistent with more recent work. For more recent reviews of passivity, the reader may consult 'argentumsolutions'<sup>4</sup> and Staehle *et al.*<sup>5</sup>

The above description of passivity refers to passivity stimulated by an externally applied potential. Passivity of real structures is, however, generally achieved in the absence of externally applied power (although it can be stimulated by application of an anodic voltage, a practice followed for anodic protection).<sup>18</sup> In the absence of an applied potential, the sink for the electrons generated by the anodic oxidation of the metal is a cathodic reaction which occurs on the passive metal surface itself. The cathodic reaction, thereby, provides the driving force. In aqueous systems, this is generally the reduction of dissolved oxygen or the reduction of water to hydrogen (or both simultaneously, depending on the potential involved) occurring on the passive oxide surface, as:

or

These same cathodic reactions also fuel the corrosion of metals if corrosion (rather than passivity) is the dominant process. It is to be noted that both cathodic reactions involve an increase in pH, while the anodic site tends to develop a decreased pH. These changes in pH over the anodic and cathodic sites can be important as they can lead to destabilization of the passive state. The state of passivity involving a cathodic reaction on the passive surface is sometimes referred to as 'chemical passivity,' as opposed to 'anodic passivity' or 'electrochemical passivity' (stimulated by an applied potential). The two phenomena are, however, very similar: both are electrochemical in nature. The only mechanistic difference lies in the fact that under chemical passivity, the transferred electrons must pass through the passivating oxide film from the metal atoms to the cathodic reactant, since the anodic reaction (metal oxidation) occurs at the metal–film interface, and the cathodic reaction occurs at the film–electrolyte interface. On the contrary, under externally applied anodic stimulation, the electrons are passed around an external circuit to a separate cathode. Electrons pass rather readily through most passivating oxide films, even those of high resistivity, because they are so thin. Other cathodic reactants may also behave as passivating agents. Their role varies depending on their nature. Thus, for example, the chromates added to the aqueous environment raise the potential of the metal by accelerating the cathodic reaction. If the potential is thereby raised into the passive regime, the metal is passivated essentially by the added chromate, which then functions as a corrosion

inhibitor. The reduced chromate also aids passivity by depositing Cr(III) into the passivating film. The earlier theory that only oxygen is required as an adsorbed layer for passivation is, of course, not tenable, since passivity can be achieved readily with alternative oxidizing agents, or with an applied potential in the absence of dissolved oxygen (or any other oxidizing agent): passivity is due to a surface film, usually an oxide, as a distinct solid phase and usually of thickness greater than one monolayer. The oxide ions required to form the film originate from water molecules, and the role of dissolved oxygen is merely that of an oxidizing agent.

Other corrosion inhibitors also enhance passivity without electrochemical reduction, by depositing insoluble oxidation products into the passivating film. For example, benzoate ions cause deposition of ferric benzoate into the oxide, but do not provide any cathodic reaction.

The phenomenon of chemical passivity can be considered by examining the polarization curves for the separate anodic and cathodic reactions, shown in **Figures 2 and 3**. The two forms of passivating agent, one that yields an accelerated cathodic reaction and the other providing insoluble reaction product, are both illustrated. Considering the fact that the anodic and cathodic reactions must occur at an equal rate, the point of intersection of these two kinetic lines in **Figures 2 and 3** describes the condition of the metal.

**Figure 2** Schematic anodic polarization curve for a passivable metal (solid line), shown together with three alternative cathodic reactions (broken line). Open-circuit corrosion potentials are determined by the intersection between the anodic and cathodic reaction rates. Cathode a intersects the anodic curve in the active region and the metal corrodes. Cathode b intersects at three possible points for which the metal may actively corrode or passivate, but passivity could be unstable. Only cathode c provides stable passivity. The lines a, b and c, respectively, could represent different cathodic reactions of increasing oxidizing power, or they could represent the same oxidizing agent at increasing concentration.

**Figure 3** Schematic anodic polarization curves for a passivable metal showing the effect of a passivating agent that has no specific cathodic action, but forms a sparingly soluble salt with the metal cation: (a) without the passivating agent and (b) with the passivating agent. The passive current density, the active–passive transition and the critical current density are all lowered in (b). The effect of the cathodic reaction c, is to render the metal active in case a, and passive in case (b).

To achieve chemical passivity, the potential must be sufficiently high to overcome the active loop (otherwise the oxidizing agent accelerates corrosion) and therefore, there must be sufficient cathodic reactant of sufficiently high driving force.

The process of formation of a passivating oxide film is anodic in nature; the driving force for its formation is raised by increasing the potential anodically across the metal–environment interface. Thus, for example, the driving force for formation of a passivating oxide film on iron by the reaction,

is raised as the potential is increased above the equilibrium potential between the metal and its oxide. Raising the potential, however, also raises the driving force toward oxidation of the metal, and thus, increases the propensity toward accelerated corrosion. The two processes of accelerated corrosion and passivation are, therefore, generally in competition, and the balance between the two can be quite delicate. Examples are abound, both in the laboratory and in the field, of passivity failure, leading frequently to rapid and sustained localized corrosion. Mechanisms describing the origins of stress-corrosion cracking and corrosion-fatigue inherently involve rupture of the passivating oxide film, and consequently, the rapid reactions that may ensue on the bare metal surface. The basis on which such forms of localized corrosion occur are well understood. In its passive state, the metal is thermodynamically very unstable. The conditions of the metal, the solution

and the potential dictate its state of passivity. If passivity is lost by whatever mechanism (e.g., by oxide film rupture or through reaction of local heterogeneities), the metal reacts anodically at high potential and therefore at a high rate, with the cathodic area occurring mainly on the surrounding undamaged passive surface. One consequence of such anodic reaction is the transport of ions to carry the current, and the generation of acidity through hydrolysis of the reaction products.<sup>19–23</sup> (Note that the reaction above describing ferric oxide formation on iron generates  $\text{H}^+$ .) If these processes generate a local solution of sufficient aggressiveness, then localized corrosion will ensue: the rate will be fast because of the high potential. If the local solution developed is not sufficiently aggressive or the reaction rate is not high enough (because the potential is too low), the site repassivates (i.e., it regenerates the passivating oxide film). These phenomena are dealt with in more detail below.

Passivity normally exists within a well defined potential range, below which the metal may activate and corrode, and above which it may transpassivate and corrode. The potential range is characteristic of the metal–environment system, and predominantly, of the available cathodic reaction. Because all anodic processes occurring through the passivating film, including the film growth, are controlled by the ionic conductance of the film,<sup>15,24</sup> a low ionic conductivity to metal cations as well as oxide ions is beneficial to passivity. Oxides of high ionic conductivity would grow to be thick, and thick oxide films are more likely to be mechanically unstable, because they are more crystalline, and more defective. The passivating film thickness is also controlled by the rate of dissolution of the oxide into the electrolyte. The electron conductivity of the oxide is of less consequence. Metals such as aluminum and tantalum, whose oxides are of low electronic conductivity, can be as passive as iron and copper, whose oxides are highly electronically conductive. Although passivity in an open circuit requires electron passage through the oxide, this is rarely a limiting step. Consideration of the variables associated with each system is therefore critical in determining the state of passivity.

## 2.02.2 Determination of the Passive Corrosion Rate

If a metal were perfectly passive and the solubility of its ions were zero, the passive corrosion rate would be

zero but it would take a long time to reach that state. This is never the case, and passivity always implies an ultimate steady state corrosion rate, and it is generally important to know that rate. This is determined as the passive current density,  $i_{\text{pass}}$ , through polarization experiments. The rate of penetration in the passive state is then  $dx/dt = Mi_{\text{pass}}/zF\rho$ , where  $M$  is the atomic weight of the metal,  $z$  is the electron number,  $F$  the Faraday constant, and  $\rho$  the density of the metal. Polarization curves as shown in Figure 1 are commonly measured by potential sweep measurements (at constant sweep rate,  $dE/dt$ ); such curves also yield a passive range of potentials. The value achieved, however, depends on the imposed potential sweep rate because at any potential the steady state value of  $i_{\text{pass}}$  takes some time to be reached. The time taken to reach the steady state, often overlooked or ignored in laboratory studies of passivity, can be measured in minutes, hours, or even days.<sup>†</sup> Fast sweep rates may, therefore, yield an erroneously high value. The passive current density is, thus, more accurately obtained at constant potential. A further feature, which can yield an erroneously low value of  $i_{\text{pass}}$ , is the presence of a cathodic reactant, such as oxygen. To overcome this, laboratory measurements are made in deaerated solution; full deaeration is, however, not possible. The lower the true passive current density, the greater is the inaccuracy in the measured value.

Measurement of  $i_{\text{pass}}$  at constant potential does not resolve this inaccuracy. The error can be recognized by measurement using a rotating disc or cylinder electrode. Variation in the rotation rate then alters the rate of oxygen transport, and an apparent reduction in  $i_{\text{pass}}$  is observed as the rotation rate increases. The constituent of passive corrosion rate forming a viably passive structure is to be questioned, and is dependent on the application. One of the most demanding states of passivity is that required by metallic surgical implant materials, where even small passive corrosion rates of metals (undamaging to the metal), which show toxicity in ionic form and whose ions are not excreted at the appropriate rate, may accumulate to significantly toxic levels. It is, nevertheless, quite common for the passive corrosion rate to be low, that a well engineered structure corroding in its passive state is visibly unchanged after very many years service.

<sup>†</sup>Editor's note: This is probably an understatement; work on Alloy 22, a highly corrosion resistant passive alloy, suggests that the passive corrosion rate falls over months or years.

### 2.02.3 The Polarization Curve

It is worthwhile to consider the general form of the anodic polarization curve, obtained when the potential of a metal is scanned in deaerated solution. Figure 4 shows a series of schematic curves which describe the onset of passivity (as shown in Figure 1) and the behavior of passive state. Such curves can only be determined potentiostatically or potentiodynamically; galvanostatic measurement of potential cannot provide the polarization curve of a passivating metal because the potential is a three-valued function of the current density. At low anodic potential (region AB) in solutions where the metal ion has appreciable solubility, the metal dissolves actively with the current rising exponentially with increase in potential (see Figure 1). Passivation commences at B and is completed at C; region BC comprises the active-passive transition. The passive current then continues to flow with further increase in potential, approximately independent of potential, until point D, F, H, or J depending upon the

**Figure 4** Schematic anodic polarization curve of a metal showing possible behavior of the passive region. AB is the active region and BC the active-passive transition. The metal is passive at potentials more positive than C. If the solution contains aggressive anions such as chloride, passivity may breakdown at D (the pitting potential), and the current rises with further increase in potential (DE) as corrosion pits propagate and nucleate. The region DE is not necessarily linear. If pitting agents are absent, but the passivating film be transpassively dissolved, then transpassive corrosion commences at F, increasing in rate with increasing potential (FG). If the passivating film is chemically and electrochemically stable, and is conductive to electrons, oxygen evolution commences at H, and increases in rate to I. The metal remains passive. If the film is stable and insulating to electrons, oxide film growth continues with further increase in potential (HJ) and the metal remains passive.

properties of the passivating film with respect to the electrolyte solution.

In solutions with a sufficient concentration of aggressive ions, such as chloride, premature failure of passivity occurs with many metals (such as aluminum, iron, nickel, and their alloys) at point D, by the nucleation of pitting corrosion. Failure of passivity is localized, and the current rises with further increase in potential (region DE), as the pits grow and more pits form. Note that the current density is usually obtained by dividing the measured current by the surface area of the specimen being tested. When localized corrosion, such as pitting occurs, the actively dissolving area is found to be very small (else, corrosion cannot be termed localized). The current density measured as such does not, thus, represent the local corrosion rate, or the penetration rate, which is in fact much faster. The rise in mean current density in region DE of [Figure 4](#) is not necessarily an exponential function of the potential. The region accommodates an increasing number of pits with increase in potential, as well as their growing surface area, with time. This region also shows a significant noise in the measured current.

In the absence of aggressive anions, the passivating oxide film may begin to be oxidized at point F to produce a soluble anion, and passivity again fails, this time by oxidative dissolution. The current rises with further increase in potential (region FG) as the dissolution rate rises. This occurs, for example, with chromium and manganese by oxidation to  $\text{CrO}_4^{2-}$  and  $\text{MnO}_4^{2-}$  or  $\text{MnO}_4^-$ , respectively. If the oxide film is stable, and is also a good electron conductor, such as with iron and nickel in neutral or moderately alkaline solutions, then point H marks the potential at which the solution begins to be oxidized. In an aqueous solution, this is the oxidation of water to oxygen, for which the standard electrode potential is 1.228 V (SHE) at 25 °C. Subsequently, the rise of current with increase in potential in region HI describes the increasing rate of oxygen evolution. Passivity here is not disturbed (unless the oxide film is damaged mechanically by the oxygen bubbles). This process can only occur if the oxide film is an electron conductor, since the oxidation of water requires the withdrawal of electrons from the water molecules through the oxide to the metal: oxidation of water occurs at the film–electrolyte interface.

Finally, if the film is stable in solution, and is a poor electron conductor, as those formed on aluminum and tantalum in halide-free environments, oxygen evolution is not possible. Raising the potential

beyond point H in [Figure 4](#) causes the film to grow further, with the current continuing to be approximately independent of potential (region HJ). It is under these conditions that high-voltage anodizing can be adopted to produce relatively thick oxide films, as described below.

For metal–environment couples, where the passivating oxide film does not break down, does not oxidatively dissolve, and does not conduct electrons readily, the only mechanism for relaxing the increasing electric field as the potential is increased is the thickening of the oxide film. The process occurs by ion conduction through the film. In fact, if the potential of aluminum immersed in a suitable anodizing electrolyte is raised suddenly to a high value, transient evolution of oxygen bubbles is observed. The oxide is, of course, a dielectric, and the sudden potential jump imposes dielectric breakdown with conduction of electrons because of the increased electric field. The effect is rapidly quenched as the barrier oxide film grows simultaneously, relaxing the electric field.

In many cases, passivating and highly electrically insulating oxide films can be grown to thicknesses of several hundred nanometers, and even micrometers; such films can be observed readily in the scanning electron microscope.<sup>24–29</sup> The applied anodic voltages can be in the region of several tens, and even hundreds of volts, and can be applied as a DC current or voltage, or as an AC voltage, depending on the required properties of the oxide. The most widely anodized metal industrially is aluminum. Although AC anodizing of aluminum imposes a cathodic half-cycle for each anodic half-cycle, oxide film reduction does not occur, contrary to what might be expected. This is because the oxide film on aluminum is irreducible. In an appropriate electrolyte, the passivating oxide film can be induced to be overlaid with a much thicker microporous oxide layer. Electrolytes that induce formation of a porous overlayer tend to be more aggressive, for example, aluminum in sulfuric or phosphoric acid. Inevitably, the porous layer is underlaid with a nonporous barrier layer (otherwise the high applied voltage would induce vigorous oxygen evolution in those areas lacking the electron-insulating oxide). The barrier layer, which is the passivating component, is thus named because it carries most of the electric field and controls the film growth current. Its thickness increases linearly with the applied voltage, consistent with the behavior of other passivating oxide films. This duplex oxide film formed on aluminum finds wide technological

applications. Anodizing of titanium to appropriate oxide film thicknesses produces vigorous interference colors, a phenomenon exploited in the ingenious art of Pederferri.<sup>30</sup>

## 2.02.4 Mechanism and Kinetics of Passivation

The basic mechanism of passivation is easy to understand. When the metal atoms of a fresh metal surface are oxidized (under a suitable driving force), two alternative processes occur. They may either enter the solution phase as solvated metal ions, passing across the electrical double layer, or may remain on the surface to form a new solid phase, the passivating film. The former case is active corrosion, with metal ions passing freely into solution via adsorbed intermediates. In many real corrosion cases, the metal ions, despite dissolving, are in fact not very soluble, or are not transported away from the vicinity of the surface very quickly, and may consequently deposit on the surface as an oxide or insoluble salt. Often these cases are not passivating because the insoluble corrosion product is deposited from the solution phase as a poorly adherent, loose, crystalline substance. Formation of rust on steel is one such example; blue and green deposits on corroded copper plumbing are another. Oxide films which are passivating are most commonly formed when they are generated directly on the metal surface without the constituent metal ions passing first into solution.<sup>31</sup> While the precise structures of passivating films remain contentious,<sup>32,33</sup> they are known to be coherent and continuous, necessarily so since any lack of continuity would provide paths for active dissolution leading to localized corrosion.

Formation of the first layer (a monolayer) of passivating oxide film on a denuded metal surface occurs easily by the loss of protons from the adsorbed intermediate oxidation products, such intermediates being common to both dissolution and passivation processes.<sup>34–42</sup> Thus, for example, the first oxidative step in the anodic oxidation of nickel is the formation of the unstable adsorbed intermediate NiOH by

Similar initial reactions occur on many metals such as iron and cobalt. This intermediate can now react further in one of the two ways. Oxidation and protonation of the intermediate to Ni(II) leads to

dissolved nickel ions (active corrosion) which are unable to passivate the metal:

On the other hand, oxidation and deprotonation of the same intermediate leads directly to passivation by:

where the subscript 'ads' represents the adsorbed intermediate, 'aq' represents the aquated metal ion in solution, and 'f' represents the oxide film. These reactions are able to proceed because the solvent, water, is effectively an infinite source, and sink, for  $\text{H}^+$ . The intermediate  $\text{NiOH}_{\text{ads}}$  is common to both the dissolution and passivation reactions. It can be regarded as an hydroxide of Ni(I) or an adsorbed OH radical; the distinction probably is not important to the case of passivation. Because of subsequent reactions, it is better considered as the compound of univalent nickel. This intermediate does not exist as a bulk species. Its existence as an intermediate is undoubtedly due to the fact that it is adsorbed to the metal surface on one side, and carries the aqueous double layer on the other. The preferential occurrence of reactions [5] and [6] depends on the solution composition, its pH, the potential, and the temperature. It is apparent that the nickel atoms involved in going from Ni to NiO via steps [4] and [6] never leave the metal surface. Formation of NiO (or the hydrated form,  $\text{Ni}(\text{OH})_2$ ) by precipitation from the dissolved nickel ions formed in reaction [5] does not lead directly to passivity. For iron, formation of oxides from dissolved  $\text{Fe}^{2+}$  via precipitation from solution leads to nonprotective rust. (Brown rusts involve further oxidation of  $\text{Fe}^{2+}$  by dissolved oxygen). Such precipitated oxides are not usually passivating. The passivating oxide formed by reaction [6] can only occur when the equilibrium potential between the Ni and NiO is reached or exceeded. Higher oxides of nickel may also impart passivity once the appropriately higher equilibrium potential is exceeded.<sup>31</sup> Clearly, such oxides form preferentially in solutions where the oxide is effectively insoluble: for many metals these are solutions of neutral and mildly alkaline pH. Nevertheless, in acidic solutions where the oxide is thermodynamically unstable relative to the dissolved metal cation, passivation can still occur (and does so on many metals, including nickel), as exhibited by chromium. Cr(III) oxide is thermodynamically unstable in acidic systems,<sup>3</sup> but the metal is still very passive in sulfuric acid (at the appropriate potentials); the implication is that the dissolution of

the passivating oxide into acidic solutions, which must inevitably occur, is very slow, and the rate of corrosion of chromium in its passive state is undoubtedly controlled by this dissolution rate. (It is chiefly chromium (III) which gives rise to passivation of alloys containing sufficient quantities of Cr, such as stainless steels and nickel–chromium alloys.)

There are, in fact, many possible steps that could be included in the basic mechanisms described above, for example, involving adsorption processes for  $\text{H}_2\text{O}$  and  $\text{OH}^-$ , and interactions among the adsorbed species. The most widely studied is the reaction of iron, but similar steps are also encountered in the anodic oxidation of many metals. These mechanisms include the same basic steps as described above.<sup>34–42</sup>

The first monolayer is generally formed before any significant film thickening occurs, because of the very strong dependence of the film growth rate on the electric field across the reacting interface. A mechanism of the type shown in eqns [4] and [6] does not necessarily involve an oxide nucleation step. Rather, it is a random oxidation of the exposed surface metal atoms until the first monolayer of oxide is complete.<sup>41–44</sup> Such a model shows that passive films may, in fact, be amorphous, with no defined crystal structure. Alternatively for some metals, an initial nucleation step may occur with two-dimensional spreading of the oxide over the surface to produce expanding circular ‘pancakes’ of oxide which link when they impinge on one another. This mechanism, which involves different kinetics, has not been found in repassivation experiments involving mechanically stripped transition metal surfaces.<sup>41–44</sup> Growth of the first monolayer of the passivating oxide causes significant reduction in the rate of oxidation of the metal, but in general, the process does not stop there.

Once the metal surface has become covered with its first monolayer of the oxide film, the metal is then separated from its environment by that oxide, and film thickening ensues: metal cations or oxide anions (or both) are transported through the existing oxide film, thereby relaxing the electric field which drives the mobile ions, until a steady state is reached. Ion migration (or vacancy migration) under the electric field controls the film growth rate.<sup>14,24,45–48</sup> As the film thickens at constant potential, the relaxing electric field across it reduces the rate of field-assisted ion migration, and the rate of film growth declines. The steady state is reached when the rate of film thickening equals the rate of film dissolution into the environment, resulting in a net constant rate dissolution of metal. Different metals display different passive

corrosion rates, and it is the numerical value of this rate which dictates whether the metal can be regarded as sufficiently passive for specific engineering purposes. Highly passive metals usually carry very thin oxides, and the electric field sustained by the overall metal–oxide–film–electrolyte interphase region is very high. For example, at a potential of 0.2 V and an oxide film thickness of 2 nm the mean electric field is ca.  $108 \text{ V m}^{-1}$ . The precise distribution of this electric field, namely the fraction lying across the film and that lying across the two phase interfaces is not known, although several models exist.<sup>47–51</sup> Similarly, the identity of the transporting ions is often not known. Although bulk oxides can often be classified as cation-vacant, anion-vacant or containing excess ions interstitially, thus dictating the mode of ionic charge transport, passive films are so thin that properties of bulk oxides may not necessarily be applicable. The effect is strikingly realized when it is considered that many passivating oxide films are often no thicker than one or two unit cells of the equivalent bulk oxide, and their transport properties may consequently differ from those of the bulk material. Only in the model of Macdonald *et al.*<sup>50,51</sup> is such a distinction drawn for the corrosion and passivation characteristics, where the model predicts that the transport of metal cations across the oxide from the metal interface to the electrolyte interface causes dissolution, and the transport of oxide ions in the reverse direction causes film growth.

Derivation of the rate of oxide film growth proceeds as follows. When the metal carrying its oxide film is at its equilibrium potential, no overpotential exists across the oxide, and the rate at which ions move through the oxide from the metal to the electrolyte equals the rate at which they move back again. Expressed as current densities, the forward rate is  $i_f$  and the backward rate  $i_b$ ; these rates are equal at equilibrium. Ions moving through the film do so via vacancies (anionic or cationic, leading to anionic or cationic migration), or interstitially. They, thereby, encounter an energy barrier which they must surmount in order to move: the width of this energy barrier is the distance between anionic or cationic sites in the oxide lattice if the mechanism is by vacancy migration, or the distance between interstitial sites if the mobile ions move interstitially. This distance is  $2a$ . The height of the energy barrier is the activation energy,  $\Delta G^*$ . Thus, at equilibrium

$$i_f = i_b = zFk \exp \left[ -\frac{\Delta G^*}{RT} \right] \quad [7]$$

where  $k$  is the rate constant,  $z$  is the charge number,  $F$  is the Faraday constant,  $R$  is the gas constant, and  $T$  the temperature. Equation [7] is an expression of the Arrhenius equation.

We now apply an anodic overpotential  $\eta$ , for film growth, and for simplicity, we regard this overpotential as being distributed entirely across the oxide film. If the oxide film has a thickness  $x$ , then the electric field across the film is  $d\eta/dx$ , which equals  $\eta/x$  if the overpotential lies linearly across the oxide film. The potential drop across the distance  $2a$  (a single energy barrier) is then  $2a\eta/x$ . The activation energy in the forward direction (i.e., with the electric field) is thereby reduced by an amount  $a\eta zF/x$ , and that in the backward direction (i.e., against the electric field) increased by an amount  $a\eta zF/x$ . Thus, under the applied overpotential  $\eta$

$$\begin{aligned} i_f &= zFk \exp \left[ -\frac{(\Delta G^* - a\eta zF/x)}{RT} \right] \\ &= zFk \exp \left[ -\frac{\Delta G^*}{RT} \right] \exp \left[ \frac{a\eta zF}{xRT} \right] \end{aligned} \quad [8]$$

Similarly, in the backward direction

$$\begin{aligned} i_b &= zFk \exp \left[ -\frac{(\Delta G^* + a\eta zF/x)}{RT} \right] \\ &= zFk \exp \left[ -\frac{\Delta G^*}{RT} \right] \exp \left[ -\frac{a\eta zF}{xRT} \right] \end{aligned} \quad [9]$$

The following parameters are constants (at constant temperature) and are simplified to

$$A = zFk \exp \left[ -\frac{\Delta G^*}{RT} \right] \quad [10]$$

and

$$B = \frac{azF}{RT} \quad [11]$$

The net current density,  $i$ , in the forward direction (i.e., producing film growth) is

$$i = i_f - i_b \quad [12]$$

and

$$i = A \exp \left[ \frac{B\eta}{x} \right] - A \exp \left[ -\frac{B\eta}{x} \right] = 2A \sinh \left[ \frac{B\eta}{x} \right] \quad [13]$$

This is the general expression for film growth under an electric field. The same basic relationship can be derived if the forward and reverse rate constants,  $k$ , are regarded as different, and the forward and reverse activation energies,  $\Delta G^*$  are correspondingly different:

these parameters are equilibrium parameters, and are both incorporated into the constant  $A$ . The parameters  $A$  and  $B$  are constants for a particular oxide:  $A$  has units of current density ( $A m^{-2}$ ) and  $B$  has units of reciprocal electric field ( $m V^{-1}$ ). Equation [14] has two limiting approximations.

- (a) When the electric field,  $\eta/x$ , is large (high  $\eta$  and/or small film thickness,  $x$ ),  $2 \sinh y = \exp y$ , and

$$i = A \exp \left[ \frac{B\eta}{x} \right] \quad [14]$$

This is commonly known as the high field equation. It is similar to the Tafel equation for activation controlled electrochemical reactions with the additional feature that the potential driving the reaction lies across an oxide film of variable thickness,  $x$ , rather than across the double layer (of constant thickness). The kinetics of oxide film growth according to this equation approximates to (but are not identical to) inverse logarithmic film growth.<sup>46,52,53</sup> The passivity of most passive metals is associated with a high electric field since most passivating films are very thin. A high electric field implies either a thin passivating film ( $x$  is small) or a high overpotential ( $\eta$  is large), or both.

- (b) When the electric field is small (i.e.,  $\eta$  is small and/or  $x$  is large),  $\sinh y = y$ , and

$$i = \frac{2AB\eta}{x} \quad [15]$$

Equation [15] is ohmic ( $i \propto \eta$  for constant film thickness): the term  $x/2AB$  can be regarded as the film resistance. The equation is identical to parabolic film growth, for which the film thickens with the square root of time at constant potential.

Because passivating films are generally very thin, passivation is normally a high field process and eqn [14] can replace eqn [13]. The same relationships can be applied to high voltage anodizing of metals such as aluminum and titanium. However, under these conditions, the oxide sometimes assumes a duplex structure, with an inner barrier layer and an outer porous layer: for these, the film thickness  $x$ , relates to that of the barrier film only, since it is largely this part which carries the applied voltage. The relationships make no assumption about the identity of the mobile ion, and are equally applicable whether the anion or the cation is mobile within the film lattice causing film growth. Because the anodic current in the passive state is approximately independent of the potential in the steady state, the above kinetic equations

imply that the thickness of the passivating oxide film increases linearly with increase in the overpotential, and therefore with the applied potential. This has been confirmed by ellipsometric analysis of the oxide film.

As the film growth rate depends strongly on the electric field across it (eqn [14]), separation of the anodic and cathodic sites for metals in open circuit is of little consequence, provided film growth is an exclusive reaction. Thus, if one site is anodic, and the adjacent site cathodic, film thickening on the anodic site causes the two sites to swap roles so that the film on the former cathodic site also thickens correspondingly. Thus, the anodic and cathodic sites of the stable passive metal 'dance' over the surface. However, if a permanent separation of sites occur, where the anodic site has restricted access to the cathodic component in the electrolyte (as in a crevice), then breakdown of passivity and associated corrosion can follow. The kinetics outlined above, first observed empirically by Güntherschulze and Betz,<sup>54</sup> were modeled by Verwey<sup>45</sup> with the rate-controlling energy barrier being that between two adjacent cation sites within the oxide film. The same basic form can be derived if the rate-controlling energy barrier is that between a metal atom on the metal surface and an adjacent cation site in the film.<sup>14,46</sup> The rate is then limited by ion injection into the film rather than by ion migration through the film. It should also be noted that the above kinetic relationships can be modified to include the other processes occurring during anodic oxide film growth, such as space charges within the film and charging of the phase interfaces.<sup>47,48,55</sup>

The point defect model of Macdonald *et al.*<sup>51</sup> draws a distinction between cation and anion mobility, with mobile cations leading to metal dissolution and mobile anions (oxide ions) leading to passivity: this model has an inherent attraction of incorporating a mechanism for metal dissolution. The procedure leads to direct logarithmic film growth (at constant potential), as does the place exchange mechanism of Sato and Cohen.<sup>56</sup> Apart from the work of Macdonald,<sup>51</sup> the passive state dissolution rate has been studied far less than the oxide film growth rate, and it is not really known why the dissolution rate of the passivating oxide should be so slow. The process of oxide dissolution has been reviewed<sup>57</sup> and is complex. The complexity of the dissolution has been exemplified by Nii,<sup>58</sup> who showed that the rate of dissolution of nickel oxide particles (with no metal substrate) in aqueous solution is strongly dependent

on trace quantities (for concentrations down to  $\sim 10^{-6}$  M) of ionic impurities in the solution. The rate of dissolution of oxides is influenced by the polarization of the oxides, a notion clearly important to the passivity of metals.

The kinetics outlined above refer strictly to single crystals, with no metallurgical defects, such as grain boundaries. Polycrystalline metals and alloys contain many such defects, and their passivation is expected to be different, especially when the defects may contain high concentrations of impurity atoms, such as sulfur segregated in the grain boundaries in steels. The kinetics of passive oxide film growth, as measured electrochemically, may well be dominated by the passivation of the grain faces because of their overwhelmingly large surface area. However, the long-term stability of the passive state may become dominated by the grain boundaries (as in the case where intergranular corrosion occurs) or by inclusions, precipitates or other microscopic defects. This feature is very important in consideration of measured passive corrosion rates.

Determination of the kinetics of passivation can be carried out potentiostatically, provided any previously formed oxide film, such as that formed by prior exposure to air is first removed. Such removal can be achieved by the reduction at low potential for fairly noble metals, but cannot be readily achieved for the relatively base metals such as chromium, aluminum, or titanium. Some metals, such as iron, become charged with hydrogen during cathodic reduction of their oxide films, a process predicted by the thermodynamics of the two processes. Many alloys may undergo changes in surface composition and structure during applied electrochemical reduction, and subsequent reoxidation kinetics may not be representative of the true alloy surface. Under these conditions, the electrochemical kinetics of oxide film growth can only be determined if the preformed oxide film is stripped away mechanically, by cutting with an inert scribe, such as diamond, sapphire, or boron nitride.<sup>59–66</sup> Such techniques then allow measurement of the kinetics of passivation through potentiostatic current transients or through galvanostatic potential transients. Passivation in open circuit is also amenable to such examination.<sup>66</sup>

## 2.02.5 Thermodynamics of Passivity

The thermodynamics of passivity, primarily due to Pourbaix,<sup>3</sup> are usefully considered by examining the

equilibria between metals and their oxides in contact with water. Before doing so, however, it is worth bearing a number of points in mind. First, the passivating oxide film is in many cases so thin that its thermodynamics may not be identical to that of bulk oxides. This is already implicit in the discussion of the adsorbed NiOH intermediate in nickel oxidation. The matter is of particular importance when it is realized that the two faces of the oxide film, one in contact with the metal and the other in contact with the environment, are so very different. By nature, the passive film must therefore be regarded as being extremely anisotropic in the sense that its dimensions are very much larger in the two directions parallel to the metal surface than in the third dimension, which is perpendicular to the metal surface. Second, the electric field across any existing passivating oxide is very large in the direction perpendicular to the metal surface and insignificant in the parallel direction, adding to its anisotropy. Finally, in the case of engineering alloys such as stainless steels, it is frequently difficult to ascribe the passivating oxide film to a known stoichiometry or structure, and the use of thermodynamic data of known bulk oxides is open to question. This problem is clearly less pronounced for pure metals. Nevertheless, consideration of the thermodynamics of standard bulk metal oxides can still provide surprisingly good agreement with observation, and can often be used effectively and predictively.

As with all determinations of thermodynamic stability, we commence by defining all possible stable phases, and their standard chemical potentials. For most metals there are many such phases, including oxides, hydroxides, and dissolved ions. For brevity, only the minimum number of phases is considered. The simplest system is a metal M, which can oxidize to form a stable dissolved product,  $M^{2+}$  (corrosion), or to form a stable oxide MO (passivation). In aqueous environments, three equilibria can thereby be defined:

The equilibrium potentials ( $E$ ) for reactions [16] and [17] are then given, respectively, by the Nernst equation:

$$E = E^\circ - \frac{RT}{2F} \ln \frac{[M]}{[M^{2+}]} \quad [19]$$

$$E = E^\circ - \frac{RT}{2F} \ln \frac{[M][H_2O]}{[MO][H^+]^2} \quad [20]$$

where the brackets represent the activities of the components and  $E^\circ$  is the standard equilibrium potential (or standard electrode potential) for the reaction. The value of  $E^\circ$  is readily calculated from the standard chemical potentials of the relevant components. By defining the standard states of the metal, the oxide, and the solvent as the pure components (unit mole fraction), the only solution variables are the  $M^{2+}$  and  $H^+$  activities, provided the metal, the oxide and the water are pure. Thus, in decadic logs, eqns [19] and [20], respectively, are

$$E = E^\circ + \frac{2.303RT}{2F} \log[M^{2+}] \quad [21]$$

and

$$E = E^\circ + \frac{2.303RT}{2F} \text{pH} \quad [22]$$

For the nonelectrochemical reaction [18], the equilibrium constant ( $K$ ) for the reaction is written as

$$\text{pH} = -\frac{1}{2} \log K - \frac{1}{2} \log[M^{2+}] \quad [23]$$

The thermodynamic equilibria are then represented for fixed dissolved metal ion activity as a plot of  $E^\circ$  against the pH of the solution, as shown in **Figure 5**, noting that eqn [21] is independent of pH and eqn [23] is independent of potential. The Figure shows that oxide stability is achieved at potentials greater than  $E^\circ$  for reaction [22] and in solutions of pH greater than that described by eqn [23]. If the potential is greater than  $E^\circ$  for reaction [21] and the pH more acidic than that given by eqn [23] the metal corrodes to give  $M^{2+}$ . If the potential is low, the metal is immune to oxidation. The diagram thus describes the thermodynamically stable phases of the metal in terms of regions of passivity, corrosion and immunity as a function of  $E$  and pH. The position of the lines representing eqns [21] and [23] depends on the value of the selected  $M^{2+}$  activity. It is common (but not necessary) to adopt a concentration of  $10^{-6}$  M for this purpose, but the issue is critical in determining the relative thermodynamic stabilities of the dissolved component and the oxide. The fact that only equilibria with water are considered in the example specifies that any dissolved components present in solution have no effect on the reactions of the metal and its components. Reactive ions such as  $Cl^-$  dissolved in the solution modify the equilibria by their own free energy considerations. Although more complicated,

**Figure 5** Schematic potential–pH diagram for a metal M in equilibrium with water in the absence of complexing species. Line a represents eqns [16] and [21]. Line b represents eqns [17] and [22]. Line c represents eqns [18] and [23]. The stable phases are marked in bold. The metastable phase is in parentheses. The broken line is an extrapolation of eqn [22] and indicates possible metastable passivity.

such systems can nevertheless be thermodynamically calculated if the formation constants of the associated complexes and compounds can be defined.

The line representing eqn [22] is shown broken for pH more acidic than eqn [23]. The oxide is not thermodynamically stable in this region of pH, and for true thermodynamic equilibrium should not be shown at all. Many metals, however, still show a passive region in this state, provided the potential is higher than that given by eqn [22]. The origin of this is, of course, kinetic. If an oxide film does form, and if it is very slow to dissolve (it must dissolve since the oxide is unstable relative to the dissolved ion) then passivation ensues. The state has sometimes been referred to as ‘metastable passivity’.<sup>‡31</sup> While it might reasonably be rationalized that passivity is brought about by a very low solubility of the dissolved metal ion, thereby effectively preventing metal dissolution through formation of a sparingly soluble oxide layer, this is not a necessary condition for passivity. Certainly, a thermodynamically stable oxide layer is more likely to generate passivity. However, the existence of the metastable passive state implies that an oxide film may (and in many cases does)

still form in solutions in which the oxides are highly soluble. This occurs for example, on nickel, aluminum and stainless steel, although the passive corrosion rate in some systems can be quite high. What is required for passivity is the rapid formation of the oxide film and its slow dissolution, or at least the slow dissolution of metal ions through the film. The potential must, of course, be high enough for oxide formation to be thermodynamically possible. With these criteria, it is easily understood that a low passive current density requires a low conductivity of ions (but not necessarily of electrons) within the oxide.

It is not possible to predict thermodynamically whether or not a metastable passivating film forms in acidic solutions. Thus nickel, cobalt, and aluminum exhibit metastable passivity in acidic solution (although not necessarily practical); but cadmium does not. Metals which display metastable passivity, particularly in acidic solutions, often show polarization curves whose potential ranges can be correlated with the thermodynamic potentials of the potential–pH (Pourbaix) diagram (Figure 5). Thus, for example, nickel in sulfuric acid shows an active loop between the potentials represented by lines a and b in the Pourbaix diagram; as the potential is increased further, passivity commences when the potential exceeds approximately that described by eqn [22], observed as an active–passive transition. Because metastable passivity is a kinetic phenomenon, however, a significant overpotential may be required to produce it. Where more than one oxide may exist, it is not necessarily associated with the lowest metal oxidation state that provides the best state of passivity. On thermodynamic grounds alone, one predicts the classic form of the anodic polarization curve, in which the passive range of potential is preceded (at lower potential) by an active loop as shown in Figures 1–4. From the point of view of corrosion engineering for acidic systems, metastable passivity is of the utmost importance. Most structural metals designed for acidic environments are used in this state of metastable passivity. These are often chromium-containing alloys (stainless steels and nickel-based alloys), since chromium shows extremely good metastable passivity in acidic environments.

It is worth emphasizing that the position of lines representing equilibria with the dissolved species,  $M^{2+}$ , depend critically on the solubility of the ion, which is a function of pH. For example, iron in moderately alkaline solution is expected to be very passive,<sup>3</sup> and so it is in borate solutions (in the absence of aggressive ions). However, the anodic polarization curve still shows a small active loop at low potential.<sup>68</sup>

<sup>‡</sup>Editor’s note: This phenomenon has been analyzed in more detail by Macdonald.<sup>67</sup>

The form of [Figure 5](#) is common among many metals in solutions of acidic to neutral pH of non-complex anions. Some metals such as aluminum and zinc, whose oxides are amphoteric, lose their passivity in alkaline solutions, a feature reflected in the potential–pH diagram. This is likely to arise from the rapid rate at which the oxide is attacked by the solution, rather than from direct attack on the metal, although at low potential, active dissolution is predicted thermodynamically.<sup>3</sup> The reader is referred to the classical work of Pourbaix<sup>3</sup> for a full treatment of potential–pH diagrams of pure metals in equilibrium with water.<sup>8</sup>

### 2.02.6 Chemical and Electrochemical Passivity

Passivity is provided and maintained by the appropriate cathodic reaction such as reaction [\[1\]](#) or [\[2\]](#): it is a requirement of this reaction that the potential is held within the passive range. This may be achieved by the cathodic reactant in the solution, such as oxygen, or it may be applied from an external power supply. In the absence of other oxidizing agents, only reaction [\[1\]](#) or [\[2\]](#) can provide and maintain passivity. For more noble metals, reduction of water is not possible, and passivity can be maintained only by reaction [\[1\]](#). These metals are, of course, immune from corrosion (and passivation) in the absence of dissolved oxygen. Base metals such as aluminum, when bared in solution (these metals inevitably carry a prior air-formed oxide film), are rendered passive by reduction of water because the initial potential is so low.<sup>59,60,66</sup> Passivity can then be maintained by reduction of oxygen because the potential rises significantly during passivation. Passivating agents in solution may be divided broadly into two groups. Those providing the cathodic reactant are oxidizing agents and raise the open-circuit potential of the metal into the passive regime, but only in sufficient concentration. The process is shown schematically in [Figure 2](#). In insufficient concentration, such oxidizing agents raise the potential further into the active region, thereby accelerating corrosion. Such behavior is well typified by the long-known reaction between iron and nitric acid. In concentrated

nitric acid, iron is passive, but if the acid is diluted, very powerful corrosion occurs with vigorous evolution of nitrogen oxides. This process was reported earlier by Keir<sup>7</sup> and Faraday.<sup>8</sup> Many oxidizing agents fall into this category, such as chromates, molybdates, oxygen, and hydrogen peroxide acting on steels. Some oxidizing agents become aggressive in reduced form, and cannot be regarded as passivating agents; these include for example, the chlorate anion which is cathodically reduced to chloride on iron. The chloride anion can initiate pitting corrosion, particularly at high potential, and the high potential is itself brought about by the same cathodic reaction.

Other passivating agents, such as phosphates<sup>70–73</sup> and benzoates<sup>74</sup> (for steels) do not fall into this category and they have no oxidizing action. Their role in enhancing passivity is to aid formation of the passive film under the cathode present in solution. In a polarization curve, this would be observed as a decrease in the passive current density, often coupled with a decrease in the potential of the active–passive transition (see [Figure 3](#)). These chemical passivating agents act by forming highly insoluble compounds with the dissolving metal (such as ferric phosphates and benzoates). The salts are precipitated over areas of the metal surface which may become active. Presumably, a passivating oxide is then formed beneath the deposited metal salt, since the metal is no longer capable of rapid dissolution, although this has not been firmly established. The formation of azelaic acid from linseed oil<sup>75,76</sup> allows precipitation of sparingly soluble ferric azelate as a passivating agent in linseed oil-based paints. Again, the metal presumably passivates by oxide film formation beneath the deposited azelate. For these passivating agents to be effective, an oxidizing agent, such as oxygen must be present.

Chromate ions fall into both the categories, namely as both an oxidizing agent and a source of insoluble film.<sup>77,78</sup> Their oxidizing power raises the potential for a number of metal systems into the passive region. The reduced form is Cr(III), either as  $\text{Cr}_2\text{O}_3$  or as a spinel with the metal oxide of the substrate, which is deposited onto the metal surface; this is itself a passivating agent and acts as such for many metals. These prime processes render chromates as effective passivating agents, and are responsible for the use of chromates as inhibitive pigments in metal priming paints (often as zinc chromate).<sup>||</sup>

<sup>8</sup>Editor's note: Resources are now available, both as commercial programs and on the world-wide web<sup>69</sup> that allow calculation of  $E$ –pH diagrams for many metals, taking account of a wide range of dissolved and solid species.

<sup>||</sup>Editor's note: Unfortunately chromate's power as a corrosion inhibitor is matched by its toxicity, and it is now banned for most applications.

Other forms of similar chemical passivating agent act where no oxide is formed. These must be mentioned here, although their action is not truly passivating. Although the dissolution–precipitation mechanism for oxide formation on metals like iron does not generally lead to passivation, some salt films formed by precipitation of dissolved ions from solution may give rise to significant passivity. Thus, silver in acidic chloride solutions forms a very stable insoluble layer of AgCl, which reduces the corrosion rate of the metal substantially. The chloride is formed, only partially, by precipitation from solution. As such the AgCl layer is thick relative to the normally formed oxide film on metals such as aluminum or stainless steel, and results in visible tarnishing of the metal. Although the corrosion rate is thereby rendered low, the metal is not strictly passive, and tarnishing of silver by silver chloride is not only unsightly – it is slowly damaging. The behavior of lead in sulfuric acid is similar because of the low solubility of lead sulfate.

Passivity can also be enhanced by incorporating components that catalyze the cathodic reaction, thereby raising the potential. By alloying titanium with small quantities of platinum or palladium, or by implantation of these elements into the surface, the cathodic hydrogen evolution reaction is thus accelerated, and titanium becomes anodically protected in appropriate environments.<sup>79</sup> Interestingly, this simple form of anodic protection does not involve an external power supply. Platinum and palladium function as good hydrogen catalysts – they raise the exchange current density for hydrogen evolution. A similar mechanism has been proposed for the action of lead-based pigments in priming paints.<sup>75</sup>

### 2.02.7 Passivation in Nonaqueous Liquids

Far less is known of the corrosion and passivation of metals in nonaqueous solvents and solutions,<sup>80</sup> and the topic can be mentioned only briefly here. The prime requirement for passivity of metals in water is the formation of an oxide film by anodic reaction with oxygen obtained from water. This is not always available in organic solvents. Thus, polarization of nickel in methanol containing sulfuric acid<sup>81</sup> shows no passive region in solutions containing less than 2 wt% water, but shows an increasingly large passive potential range, and lower passive current density, as the water content is increased above 2 wt%. Passive oxide formation arises from reaction with the water

component. Reaction of the metal with the methanol component to produce the oxide is clearly not possible. Some metals can react with the methanol component of methanolic solutions, but such reaction produces the nonpassivating methoxide rather than the oxide, and results in corrosion. The effect is seen clearly by the reaction of titanium with alkaline methanol solutions.<sup>65</sup> Generally, the effect of chloride in inducing pitting corrosion and stress corrosion cracking in metals such as titanium is increased substantially as the water content of the methanol solution is reduced, demonstrating the destabilizing effect of the reduced water activity on the stability of the passive state. Both passivation and corrosion can be difficult to predict in nonaqueous liquids in the absence of laboratory tests.

## 2.02.8 Passivity of Alloys

While the same basic mechanism for passivity of pure metals also applies to alloys, the processes involved in the passivation of alloys have an added complexity. In many cases, only one component of the alloy has the property of being passive in a particular environment. Alloys such as stainless steels, which contain highly passive components (chromium in this case), owe their corrosion resistance to the surface enrichment of the passivating component.<sup>82</sup> Thus, stainless steels resist corrosion in many acidic systems (where iron or carbon steel would be poorly passive or not passive at all) by a passivating oxide film containing Cr predominantly as Cr(III). Surface analytical techniques such as Auger electron and X-ray photoelectron spectroscopies reveal substantial enrichment of chromium in the passivating oxide film on these alloys.<sup>32,33,83–87</sup> There are only two ways by which this enrichment can arise. Either the other component (iron in the case of binary iron/chromium stainless steels) is left behind at the metal surface when the chromium oxidizes, or it is dissolved during passivation. In aqueous corrosion, particularly at ambient temperatures, it is undoubtedly dissolution of the iron component that causes chromium enrichment of passive stainless steel surfaces.<sup>64</sup> This contrasts gaseous oxidation of the same class of metals at high temperature, where chromium-rich oxide films are also formed, but iron cannot dissolve in the environment, and diffusion in the metal phase is much more rapid. Classically, a minimum amount of chromium is required in the alloy before chromium enrichment in the oxide film can be achieved: for stainless steels,

this is determined to be around 12–13 wt%. Steels containing less than this amount of chromium are not regarded as stainless. The basis of this is as follows. In environments, corrosive towards iron but passivating towards chromium (such as sulfuric acid), iron dissolves selectively from the surface of the alloy, and so the surface concentration of chromium increases to a level where the basic chromium-rich oxide film can cover the surface completely: the metal is then passive. This film contains significant quantities of Cr(III), but iron ions are also found in its structure, generally decreasing towards the film–electrolyte interface. Steels containing greater than about 12–13% chromium show a dramatic improvement in their passivating properties, in comparison to those of lower chromium content.<sup>88</sup> Analyses of such oxide films are performed using *ex situ* surface analytical techniques, such as Auger electron spectroscopy, X-ray photoelectron spectroscopy, and secondary ion mass spectrometry coupled with some form of depth profiling. Most such analyses performed to date have been carried out on surfaces exposed to the solution for relatively less time (seconds or minutes), despite the fact that steady-state passivity of stainless steels takes much longer to achieve. It is not known whether, after a sufficiently long period of exposure, the oxide film on stainless steel is composed entirely of chromium oxides.

The ease with which stainless steels can passivate increases with the level of chromium within the alloy, and hence, materials with higher chromium content are more passive (i.e., conduct a lower passive current density) and passivate more readily (i.e., the critical current density is lower and the active–passive transition is lower in potential). They are also passive in more aggressive solutions: the pitting potential is higher.

The precise mechanism by which surface enrichment of chromium through dissolution of iron in stainless steels occurs is still under some debate.<sup>64,89–91</sup> For alloys which are single-phase solid solutions, the phenomenon is readily understood if the passivating element is the major component of the alloy. The corrodible element then simply dissolves from the metal surface enriching the surface with the passivating element which then completes its passivating oxide. However, far less than 50% chromium is required to achieve passivity. Examination of the repassivation of stainless steels shows evidence of dissolution of the corrodible components from the film as it grows.<sup>64</sup> Excess iron ions in the film are dissolved and replaced by chromium ions from the metal, progressively enriching the film with chromium until passivity is

reached. However, the process may not be so simple. Recent ideas of percolation through binary alloys involve dissolution of individual and clusters of iron atoms from the alloy surface.<sup>89–91</sup> The residual chromium atoms are able to diffuse over the surface, progressively uncovering iron atoms and iron atom clusters. These are dissolved until there is sufficient chromium on the surface to link up into a continuous passivating network. The threshold concentration of Cr in the alloy ( $\sim 12\%$ ) is then determined as the percolation threshold below which interlinked networks of iron atom clusters exist through the alloy, and it is no longer stainless. Above this threshold composition, continuous percolation clusters do not exist and the alloy is passive and stainless. The attraction of this model is that its concepts can be extended to the nucleation of pitting corrosion of stainless steels<sup>92</sup> (see below). The distinction between the two modes of iron dissolution and associated chromium enrichment is, however, a fine one.

Stainless steels show another interesting feature. At high potentials, passivation by an oxide rich in Cr(III) is lost since the Cr(III) component of the oxide is transpassively dissolved in chromate ions (line FG in [Figure 4](#)). In solutions in which iron oxides are stable at high potential (mildly alkaline) and the metal does not undergo pitting corrosion, the resulting iron oxide can then provide some passivity: the roles of the two components of the alloy are thus reversed. If the nonchromium components of the steel are also not passive at high potentials, the metal corrodes transpassively. Very powerful oxidizing agents can bring about transpassive corrosion of stainless steel. Under normal conditions of use in dilute aqueous solutions, however, these high potentials would not be achieved, and chromium provides the prime passivity of these materials.

For stainless steels to remain passive, the level of chromium defined by the bulk composition must be maintained throughout the entire metal matrix. If local regions exist within the alloy microstructure where the chromium level is depleted, these become susceptible to localized corrosion, and increasingly so as the chromium content is reduced. Ultimately, if the chromium content is reduced locally below  $\sim 12\%$ , this region no longer carries the composition of a stainless steel, and corrodes as a nonstainless steel alloy. However, any reduction in the local chromium concentration of the alloy matrix is deleterious to passivity, since these alloys become progressively less passive as the chromium concentration is decreased. Such conditions are found under sensitizing heat treatments, commonly in or around welds (the heat-affected zone).

In these regions, at the appropriate temperature, chromium carbides precipitate in the grain boundaries depleting the matrix around the carbides of chromium.<sup>88</sup> The grain boundaries may then activate in service under conditions where the grain matrix is passive.

In multiple-phase alloys, the situation is different. The passivity of each phase is of importance, but there can also be a significant synergy between the behavior of adjacent phases. The presence of copper-rich precipitates in aluminum alloys containing the element accelerates the cathodic reaction locally because the exchange current density for the cathodic reaction on the relatively noble precipitate is higher than it is on the surrounding aluminum matrix. In passivating electrolytes and in the absence of pitting agents such as chloride, passivity is thus enhanced because of the increased potential. However, in the presence of chloride, the potential may be raised into the pitting regime, and passivity then becomes degraded. Aluminum alloys containing more noble alloying elements such as copper or iron are generally less resistant to pitting corrosion than pure aluminum.

### 2.02.9 Compositions of Passivating Oxide Films

The composition, structure and even thickness of passivating oxide films on metals are in fact extremely difficult to determine, mainly because these oxide films are so thin, and are 'held together' by the compositions of the interfaces (with the metal and with the electrolyte) as well as by the high electric field they carry. Many methods of determination are *ex situ* techniques, requiring removal of the specimen from the electric field as well as from the electrolyte. These methods include Auger electron spectroscopy (AES), X-ray photoelectron spectroscopy (XPS) and secondary ion mass spectrometry (SIMS), as well as X-ray diffraction (XRD).<sup>32,33</sup> A range of *in situ* methods, such as ellipsometry, frequency response analysis<sup>#</sup> and photocurrent spectroscopy are also used to provide information on the passive film.<sup>32,33</sup> These techniques, however, give more indirect information; they do not present compositional or structural information directly, but probe other properties of the passive interface, from

which more detailed understanding must be inferred. The new techniques of scanning tunneling and atomic force microscopies, which can be used *in situ*, may yield some information in the future.

The thickness of the oxide film is most readily determined by cathodic reduction, provided the film is cathodically reducible and the reduction is 100% current efficient. The cathodic charge involved then determines the film thickness for films of known composition. The method is suitable only for more noble metals, and for most structural metals it is not relevant. Film thicknesses determined by ellipsometry have been used successfully, but assumptions of the refractive index must be made. The passivating film on iron is determined to be  $\text{Fe}_3\text{O}_4$ ,  $\gamma\text{-Fe}_2\text{O}_3$  or  $\text{FeOOH}$ , depending on the conditions under which it is formed.<sup>3,32,33</sup> The thickness of the film formed in borate buffer solutions is up to  $\sim 4\text{--}5$  nm, the value depending on the potential at which it is formed. The thickness is a linear function of potential. There is now significant evidence that the  $\text{Fe(III)}$  film which passivates iron contains some  $\text{Fe(IV)}$ ,<sup>93</sup> a phenomenon which may account for the sometimes necessarily high overpotential required to passivate the metal. Surface analyses of passive films on iron, as well as other metals such as aluminum and stainless steel, show that the outer surfaces are usually hydrated, equivalent to hydroxide ions forming part of the outer structure in place of oxide ions.<sup>94-96</sup> This is, of course, only to be expected from film growth in aqueous solution. The inner regions of the films tend to be less hydrated or not hydrated at all. The passivating oxide on aluminum is reckoned to be amorphous, but crystallizes with increasing thickness during anodizing.

The incorporation of anions from the electrolyte, such as borate and carbonate, into the oxide has also been shown to occur on iron and cobalt,<sup>97</sup> such anions being restricted to the outer layers of the film. Attempts to determine chloride incorporation into passive iron surfaces from chloride-containing electrolytes have met with contradictory results, and it is still not known whether or not chloride incorporation is a precursor step to pitting corrosion.<sup>32,33,98-101</sup> Neither is this mechanistically important, but vexed question have been answered unambiguously for other metals.

The oxide film composition on alloys is inevitably more complex; some discussion of chromium-containing alloys is given above. Generally, and not surprisingly, the components of the alloy are to be found in the passivating oxide film,<sup>101</sup> but the role that these play in determining passivity and its breakdown is far

<sup>#</sup>Editor's note: now generally known as electrochemical impedance spectroscopy (EIS).

more open to question. Stainless steels show the presence of iron, chromium, and nickel in the oxide (and molybdenum for alloys containing the element), with elemental ratios that depend on pH and potential. By various *ex situ* techniques, chromium is found in (III), (IV), and (VI) oxidation states in varying proportions.<sup>32,33,84–87,101</sup> The reasons why changes in the oxide film composition should improve passivity and resistance to breakdown remain speculative.

## 2.02.10 Breakdown of Passivity and Pitting

Probably less surprising than the phenomenon and characteristics of passivity itself, is the breakdown of passivity, and the very high rate of localized corrosion that can ensue. The passivating oxide film is extremely thin, and its existence and stability depend significantly on the composition of the environment and the very high electric field it carries. It is in essence fragile, chemically, electrochemically, and mechanically, but the fragility depends on the metal and the environment as a system. Mechanical breakdown of the oxide film arises when the material is under tensile stress and can give rise to stress-corrosion cracking or corrosion fatigue. Mechanical breakdown can also arise from an erosive or cavitative action from the environment. These processes generate a fresh metal surface, the reaction of which can be twofold. In suitably quiescent environments, the bare metal surface repassivates, and the electrochemical reaction with the environment causes no significant damage, although a continuing erosive action does lead to loss of material through wear. During corrosion fatigue too, the regrowth of the passivating film over the surface can help wedge open an incipient crack during the compressive half-cycle, allowing mechanical crack growth.\*\*

Chemical breakdown of passivity occurs naturally enough if the potential is lowered into the active regime (region AB in Figure 4). This can occur if the cathodic reactant supporting passivity, such as oxygen dissolved in the electrolyte, is depleted, as occurs locally in crevices or occluded regimes of the

structure. Chemical breakdown also arises at high potential in the presence of aggressive ions, usually anions, which interact with the metal enhancing dissolution (region DE in Figure 4). The most common aggressive anion is chloride, aggressive to very many passive metals. In such cases, absence of the aggressive ion would impose passivity at the same potential: the process is, thus, essentially different from crevice corrosion.

Localized corrosion can occur if the passivating element of an alloy is locally depleted from the matrix. This may occur in the sensitized regions of stainless steels for example, as outlined above. Other alloy components too, may be deleterious towards the passivity of alloys. For example, the presence of significant quantities of sulfur as an impurity in ferrous- and nickel-based alloys is generally degrading towards passivity.<sup>23,33,102,103</sup> Sulfur is incorporated into the oxide film or accumulates at the metal–oxide interface; the element retards the formation of the oxide film and catalyses dissolution of iron and nickel, often remaining adsorbed on the dissolving metal surface. In extreme cases, a sulfide film forms on the metal surface, which is nonprotective. Appropriate heat treatment of such alloys allows segregation of the sulfur to the grain boundaries or precipitation of sulfides, both leading to very high local concentrations of sulfur and premature failure of passivity at these sites.

Where the environment is potentially corrosive, however (i.e., contains aggressive ions), even though the overall surface remains passive, corrosion can advance into the bare metal surface. The question is, how can this happen? In stress corrosion cracking attack occurs mainly around the active–passive transition (BC in Figure 4), where oxide film growth still occurs, but the state of passivity is potentially unstable, because of the proximity in potential of the active region (AB in Figure 4). Dissolution occurs simultaneously with repassivation (regrowth of the oxide film). A small ohmic resistance in the electrolyte between the external cathodic area and the anodic incipient crack tip may be sufficient to lower the potential of the crack tip into the active regime. Alternatively, a small increase in acidity developed at the crack tip as a consequence of anodic reaction may enlarge the active loop a little by raising the potential of the active–passive transition locally. Some anodic reactions at the crack tip may cause local brittleness, such as dealloying or the diffusion of cathodically reduced hydrogen in atomic form into the metal ahead of the crack tip. These processes allow repeated rupture at the crack tip, even if it

\*\*Editor's note: This statement is a little misleading. Wedging open of a crack by corrosion product increases the minimum stress intensity factor without affecting the maximum stress intensity factor, thereby reducing  $\Delta K$ , and hence fatigue crack growth rate. This process is known as oxide-induced crack closure. However, wedging by corrosion product can lead to tensile stresses at the crack tip that enhance SCC crack growth rate.

has already repassivated, because of the embrittled local metal matrix. Stress corrosion cracking also occurs near the passive–active transition at higher potential when such a transition is available (near point D in [Figure 4](#)). In this case, chloride undoubtedly enhances the ability of an incipient crack to propagate by enhancing dissolution at the crack tip, even though the pitting potential (the potential of point D) is not necessarily exceeded.

There are many forms of pitting corrosion (the formation of holes by corrosive action). The various forms have been reviewed by Szklarska-Smialowska.<sup>104</sup> Sometimes activation of a steel brought about by lowering the potential from the passive potential regime into the active regime produces etch pits, a form of uneven corrosion associated with different crystal planes within the metal. This process is less sensitive to the type of anion present, and more associated with the pH changes that occur during activation in unbuffered solutions. The pitting process considered here is a process involving the formation of small holes in an otherwise passive surface as a consequence of the aggressive action of a component of the electrolyte. It is a form of localized corrosion which involves loss of passivity locally, but does not require a stress (although it may be enhanced by a stress). It usually occurs at high potential, where one might expect passivity to dominate. In pitting corrosion, passivity is lost or ruptured through the chemical or electrochemical action of a specific component of the environment. The most commonly encountered pitting agent in aqueous electrolytes is chloride, although some other anions may also induce pitting. Notably, these are the other halides. Sulfur oxyanions such as thiosulphate,<sup>23,105</sup> and indeed sulfide ions, are conducive towards pitting corrosion in ferrous materials and nickel-based materials. It is of some consequence that most anions capable of causing pitting in particular metals also induce stress corrosion cracking of the same metals, although the converse is not necessarily true. Many metals undergo pitting corrosion in chloride solutions of sufficient concentration; these include steels and stainless steels, nickel, copper, and aluminum, and their alloys, and many more.<sup>††</sup>

<sup>††</sup>Editor's note: It is a requirement for pitting by the mechanism discussed here that the bulk of the component is passive in order to provide a large cathode area to drive the local anode. Consequently, carbon steels do not suffer from this form of pitting in neutral chloride solutions, since steel is not passive in such solutions. However, steels may suffer from transient localized corrosion in neutral chloride solutions, such as seawater, due to the presence of mill scale and/or the local effects of sulfur derived from sulfide inclusions.

A few metals are resistant to chloride-induced pitting, including chromium, titanium, and tantalum, but they are not necessarily immune to pitting, only that they are resistant. Some other anions may also induce pitting but outside the normally encountered range of corrosion potentials, and are therefore not regarded as specific pitting agents. For example, nitrate ions, which passivates towards aluminum under normal potentials, induce pitting in dilute nitric acid solutions at high potentials. Such potentials are only accessible through application of an external voltage source.

Precisely how these anions nucleate pitting in a passive metal surface is still largely unsolved, although a range of models exists. Pits in chloride solutions are often rare events.<sup>23,106</sup> In stainless steels, pits can be very widely spaced apart, and most of the surface is passive. Pit propagation rates, are however, very fast: a propagation rate equivalent to a current density of 10–100 kA m<sup>-2</sup> is common.<sup>23,106</sup> In chloride solutions, pitting is characterized by a minimum potential, called the pitting potential<sup>104</sup> (point D in [Figure 4](#)). Only above the pitting potential is pitting observed to occur. The metal is in essence passive below this potential, and this is a commonly used design criterion. However, detailed examination of the passive region (i.e., above the passivation potential and below the pitting potential, the region CD in [Figure 4](#)) of steels and stainless steels shows that the passive current is more noisy in chloride solutions than it is in the absence of chloride.<sup>23,106–108</sup> The origin of this noise is the nucleation and propagation of 'metastable' pits (also sometimes called unstable pits). Metastable pits are those which grow for a short period and then die through repassivation.<sup>23,106–111</sup> These are observed both below and above the pitting potential. Although these metastable pits do not generally cause significant damage to the metal, apart from a degree of microscopic surface roughening, they are evidence that passivity is not fully stable in the presence of chloride ions, even below the pitting potential. For these materials at least, the pitting potential (sometimes called the breakdown potential, erroneously, since breakdown of passivity occurs at lower potentials for ferrous materials) is not a pit nucleation potential: it can only be regarded as the minimum potential for stable pitting. Pits which are stable propagate almost indefinitely, either until total penetration of the metal, or until they are large enough to be washed out by the bulk electrolyte. Such noise in the current can be observed throughout the passive range of potential if the experiment is carried out carefully enough.<sup>106</sup>

The pitting potential (point D in [Figure 4](#)) is sometimes treated as a type of equilibrium potential. There are empirical reasons for this. The pitting potential is often observed to decrease linearly with  $\log(\text{Cl}^-)$  (the chloride activity or concentration), giving an apparently Nernstian form.<sup>104</sup> However, observation of metastable pitting at potentials well below the pitting potential probably precludes this notion. In addition, if the potential sweep direction is reversed at point E, the polarization curve shows strong hysteresis. The negatively moving sweep lies at higher currents, and the potential at which the pitting metal repassivates is much lower than point D. (The point where the metal repassivates in the negative sweep is sometimes called the repassivation potential.) It must also be noted that the pitting potential itself depends on the prior surface treatment of the metal, such as the surface roughness.<sup>112</sup> These facts are inconsistent with the pitting potential describing some simple electrochemical equilibrium. The pitting potential is nevertheless an extremely useful engineering parameter.

Pitting corrosion requires an incubation period or induction time to nucleate.<sup>113,114</sup> Even after initial nucleation, further events are sporadic in time. Several possible mechanisms of nucleation have been put forward. Complexing of metal cations on the surface of the film has been proposed to lead to local dissolution of the oxide,<sup>113</sup> the site then receding to the metal surface. Alternatively, chloride migration through the oxide film may lead to its accumulation as the metal chloride at the metal–film interface. This, if it occurs, could well lead to mechanical failure of the film by bursting, since metal chlorides are of greater molar volume than the corresponding oxides. The notion is appealing since it provides for a high local chloride concentration at the metal–film interface once the film is ruptured, providing an immediate pit propagation path. Film rupture could instead be induced by condensation of vacancies at the metal–film interface.<sup>51</sup> The idea of mechanical film rupture carries the added appeal that pitting events on iron microelectrodes observed potentiostatically show an initiating very fast current spike.<sup>107,115</sup> The event is microscopically violent. Recent observations with stainless steel microelectrodes show that pits here are also initiated with a violent current jump.<sup>116,117</sup> The magnitudes of the events are very small, generally up to some hundreds of picoamperes, indicative not of a low reaction rate, but of the microscopic size of the nucleation event. Interestingly, many of these nucleation events show

no propagation stage at all, not even in a metastable pit, but die immediately after nucleation. The implication is that while pit growth may be a rare event over the metal surface, the nucleation event may in fact be rather common. The same nucleation mechanism may not be applicable to all metals which pit in chloride solution, although current fluctuations are observed from aluminum in chloride solutions below the pitting potential. It has also been suggested that passive films may always undergo continuous breakdown/repair events on a microscopic scale, even in solutions which are fully passivating. This interesting idea takes the nucleation event away from the properties of the aggressive chloride anion. Chloride would then serve merely to propagate pits from these nuclei, and prevent their repassivation.

Steels and stainless steels show preferential nucleation of pits at inclusions, most notably sulfide inclusions.<sup>23,118</sup> Other sulfur-rich regions in ferrous and nickel-based alloys may also lead to premature failure. It has been shown that accumulation of sulfur on the surface of these materials retards passivity and enhances dissolution of the metal. These effects occur in any solution in which the metal shows an active region, and are also preferential pitting sites in the presence of chloride. A recent notion<sup>92</sup> for pit nucleation in stainless steels suggests that iron-rich clusters found randomly distributed in the metal structure are active when they become exposed to the electrolyte, since they do not carry sufficient chromium to allow their passivation. These are the pit nucleation sites. They become progressively exposed to the solution through the normal passive dissolution rate. This model cannot be generally applicable to pitting corrosion since it cannot account for pit nucleation in single component metals, such as iron and aluminum. In fact, any site on the metal surface capable of depassivation for any reason, is a potential pit nucleation site. For it to develop into a pit simply requires an anodic reaction capable of procuring a more aggressive anolyte, as outlined below.

The fact that amorphous metals show a higher resistance to pitting corrosion than their polycrystalline counterparts can offer more than one explanation. Such amorphous metals made from iron, chromium, and nickel simulate the stainless steel and show significantly high pitting potentials.<sup>118–121</sup> These alloys are usually made with significant quantities of nonmetallic element additions such as boron in order to retard crystallization during quenching from the melt. Such elements, which are found in the oxide film,<sup>122</sup> may aid

passivity and inhibit pit nucleation by aiding amorphization of the passive film, or by their own specific chemical action. More probably, however, it is the absence of metallurgical defects such as grain boundaries and inclusions which inhibit pit nucleation.

Once nucleated, anodic reaction at the incipient pit then requires a corresponding cathodic reaction on the surrounding passive surface if the metal is pitting in an open circuit, or at the counter electrode if pitting is carried out potentiostatically. Anodic reaction generates cations by dissolution, and  $H^+$  by hydrolysis of the dissolved cations. Acidity is also generated if the metal repassivates. Both the metal cations and  $H^+$  require neutralization, accomplished by ingress of anions. If chloride is the only available anion, its local concentration increases; the locally higher chloride concentration enhances local metal dissolution, and prevents repassivation.<sup>123</sup> The enhanced dissolution then draws more chloride into the now propagating pit, enhancing dissolution even further. Growth of the pit, is in essence, fuelled by its own reaction products: it is a feedback mechanism. The process is sometimes termed autocatalytic. Pit growth is further supported by the lower local pH. The pit anolyte becomes a saturated (or near-saturated) solution of the metal chloride, and is highly acidic. Some 60–70% of saturation of the metal chloride is required to prevent repassivation of stainless steel. It follows from this, that the presence of other anions in solution, in addition to chloride, but which are not aggressive (e.g.,  $SO_4^{2-}$ ) would reduce the ability of the metal to undergo pitting.<sup>\*\*</sup> Both ions are then transportable into the pit anolyte and it is more difficult to build up sufficient chloride to establish propagation: this is found in practice.<sup>124,125</sup>

It is apparent that such a mechanism depends strongly on the transport properties of the electrolyte components into and out of the pit. In stainless steels, pit propagation has been shown to be controlled by diffusion of ions between the pit interior and the external electrolyte.<sup>106,125</sup> The behavior of the pit site depends on its degree of occlusion: pitting is easier on rough surfaces because of the greater occlusion of sites. Surfaces of rougher finish usually display a lower pitting potential. More occluded sites can more readily retain the dissolved cations required to draw chloride into the pit anolyte.

In the early stages of pit propagation on stainless steel in chloride solution, when the pit is small, its depth alone is insufficient to act as a diffusion barrier. Diffusion is then restricted by a perforated cover which exists over the pit mouth; the perforation arises from the initiating event, and the cover exists because of undermining of the surrounding passive film as the pit expands. This perforated cover is critical to survival of the pit through the so-called metastable period of growth. Small ruptures in the cover during the metastable growth period enhance the propagation rate without terminating the pit. However, if this cover is totally lost by rupture before a critical stage in the growth of the pit, the anolyte is washed out (the outward diffusion of cations becomes fast) and the pit repassivates (hence, the term metastable). Pit growth does not then achieve stability. The critical parameter here is the product of the pit growth current density and its radius<sup>106,125</sup>; this pit stability product must reach a value of  $\sim 3 \text{ mA cm}^{-1}$  for pit growth on stainless steel to stabilize. Once the critical pit stability product is achieved, the pit can propagate without its cover. The pit depth alone is then a sufficient diffusion barrier to ensure the appropriate high chloride concentration within the anolyte, and pit growth achieves stability. Corrosion pits in chloride solution, thus pass through three consecutive steps of growth. The nucleation event is followed by metastable pit growth. Growth is metastable because the pit depth alone is an insufficient barrier to diffusion and may terminate at any point by rupture of the sustaining cover, resulting in repassivation. If the pit grows to a stage where the pit depth alone is sufficient to maintain the diffusion barrier, it enters the third stage and its growth becomes stable. Most pits die at the nucleation stage, and show no propagation. A few survive to become metastable; of those propagating metastably, only a few achieve stability.

It is worth mentioning that although pitting corrosion is generally undesirable, the process does in fact have its uses. Aluminum sheet used for the preparation of printers' lithographic sheet is subject to a preliminary treatment involving a highly controlled electrochemically induced pitting process in electrolytes based on either hydrochloric acid or nitric acid.<sup>126</sup> This procedure, termed electrograining, is designed to roughen the surface on a microscopic scale prior to anodizing. Pitting corrosion may also be induced into the nickel anodes used in nickel electroplating baths containing chloride in order to prevent their passivation, and allow continuous replenishment of the nickel ions in the electrolyte as they are removed.

<sup>\*\*</sup>Editor's note: Arguably, sulfate also acts to limit the drop in pH in the pit, since the second  $pK_a$  for sulfate (the pH at which equal concentrations of  $SO_4^{2-}$  and  $HSO_4^-$  will be present) is  $\sim 1.9$ , above the pH needed to achieve stable active dissolution.

**Symbols**

$E_b$	Breakdown potential
$E_{\text{corr}}$	Corrosion potential
$E_{\text{crit}}$	Potential above which localized corrosion may occur
$E_p$	Protection or repassivation potential
$E_r$	Rest potential
$X_{\text{crit}}$	Distance into crevice to achieve the primary pitting potential
$\Delta E$	$E_{\text{crit}} - E_{\text{corr}}$
$\Delta\phi$	IR Drop into crevice

**2.03.1 Introduction**

Crevice corrosion is a form of localized attack that occurs within occluded regions or crevices of metallic components. The attack is caused by a change in the environment of the crevice relative to the bulk solution. Usually, the term crevice corrosion is limited to describing the attack in normally passive metals and alloys (e.g., stainless steels); however, in the broader sense, the corrosion of nonpassive metals and alloys (e.g., carbon steel) by differential aeration may also be regarded as a form of crevice corrosion. Crevices occur in many engineered structures; consequently, crevice corrosion is a common form of corrosion in most, if not all, industries. Crevices can be either man-made by design, such as in washers, pipe flanges, or overlapping fuselage skins on aircraft, or they can occur naturally as a result of biofouling, deposits, and debris. Many similarities exist between crevice corrosion and other forms

of localized attack, such as pitting, intergranular attack, environmentally-assisted cracking, and dealloying.<sup>1,2</sup> In all these instances, the electrochemical and chemical conditions in the shielded surfaces within the crevice, pit, or crack, become altered when compared with the conditions on the boldly exposed surfaces. Crevice corrosion is usually described in two phases: initiation and propagation. The initiation phase may be further divided into three stages: deoxygenation, alteration of the crevice solution chemistry, and depassivation. Many variables affect crevice corrosion, both in terms of the time-to-initiation and the rate and extent of propagation. For a given material, perhaps the most important factors are the geometry of the crevice and the bulk properties of the environment. In this chapter, the emphasis is on the crevice corrosion of passive metals and alloys in aerated chloride environments since this is one of the most common types of crevice corrosion. The mechanisms of crevice corrosion are discussed, together with the effects of the many variables that affect it. Modeling and testing for resistance to crevice corrosion are discussed, as are practical design aspects and methods to minimize attack. Finally, some industry-specific examples of crevice corrosion are provided.

**2.03.2 Theories of Crevice Corrosion****2.03.2.1 Overview**

Crevice corrosion was originally described by Mears and Evans<sup>3</sup> and Uhlig,<sup>4</sup> as resulting from the development of a differential aeration cell. Mears and Evans found that accelerated corrosion occurred when a passive metal surface was in intimate contact with that of an inert material. They proposed that oxygen consumed by a cathodic reaction is replenished more slowly in the occluded region between the metal and the inert object, and that the metal surface within the crevice is deoxygenated and anodic compared to the boldly exposed surfaces outside the crevice. This difference in oxygen concentration in the solution inside the crevice relative to the bulk solution outside the crevice leads to accelerated corrosion within the crevice. Following these early observations and theories, substantial research has focused on developing a more detailed explanation of crevice corrosion.

Three general classes of theories have been used to describe the phenomenon of crevice-corrosion:

- the development of a critical crevice solution (CCS);

- the development of a critical ohmic potential difference (IR drop);
- the stabilization of metastable pits by the crevice geometry.

An ideal crevice may be described as one having a uniform gap, typically between 0.1 and 100  $\mu\text{m}$ , along its entire length or depth, and it is formed between the substrate and another surface that may be metallic or nonmetallic, as shown in **Figure 1**.

Ideal crevice geometries rarely exist even in well controlled laboratory experiments. As the crevice gap gets narrower, crevice corrosion is more likely to occur due to restricted mass transport. In addition, as the gap narrows, the surface finishes on the two materials forming the crevice become increasingly important. Also, the effect of surface finish makes it difficult to accurately characterize the crevice gap as is illustrated in **Figure 2**.

### 2.03.2.2 Critical Crevice Solution

Work on crevice corrosion modeling in the late 1960s and the early 1970s focused on the growth stage of crevice corrosion.<sup>5,6</sup> The work of Crolet and Defranoux<sup>7</sup> in 1973 represents the first attempt to model the initiation stage of crevice corrosion. Crolet and Defranoux modeled the time it takes to develop a critical chemical environment (low pH and high halide concentration) within a crevice as a function of crevice geometry, alloy composition, and bulk

**Figure 1** Schematic of an ideal crevice geometry.

solution chemistry. The development of a CCS chemistry has been used successfully by several researchers to rank alloy performance.<sup>6,8–10</sup>

In 1978, Oldfield and Sutton<sup>5,6</sup> further developed the Crolet and Defranoux model to the point that it could be used to predict crevice corrosion susceptibility. Their model considered the effect of the crevice geometry (i.e., depth and width) on the mass transport of chemical species into and out of the crevice, and then, the manner in which this process led to the formation of a critical crevice solution. Their model consisted of four stages: (1) deoxidization, (2) an increase in salinity and acidity, (3) depassivation, and (4) propagation. In their model, crevice corrosion initiation occurs when a creviced metal or alloy is exposed to an aerated, neutral pH, chloride environment. Initially, corrosion occurs over the entire surface, both within the occluded region and over the boldly exposed surfaces. In order for crevice corrosion to occur, the exposed metal must be passive in the bulk environment. Initially, metal dissolution occurs at the passive current density, which is typically of the order of  $1 \mu\text{A cm}^{-2}$  or less, and both anodic and cathodic reactions occur on all surfaces. As the solution containing dissolved oxygen is consumed at cathodic sites on the noncreviced surfaces, it is replenished from the bulk solution. In occluded regions, however, where mass transport is limited, oxygen becomes depleted and the metal surfaces within the crevice become net anodic, while the boldly exposed surfaces become net cathodic. This difference in the dissolved oxygen concentration sets up an oxygen concentration cell between the passive boldly exposed surfaces and the crevice mouth (cathode), and the occluded region of the crevice (anode). The depletion of dissolved oxygen in the solution contained within the crevice polarizes the metal surfaces in the crevice to lower, more negative potentials.

Although differential aeration is sufficient to induce crevice corrosion in certain metals and alloys, it only provides the initial driving force for crevice

**Figure 2** Schematic of hypothetical crevice geometry.

corrosion in stainless alloys. In chloride containing solutions, the iron and chromium cations, which are oxidized as they diffuse through the passive film, dissolve, and accumulate in the crevice. The limited mass transport of metal ions out of the crevice causes metal-ion accumulation, and to preserve electroneutrality, anions (e.g., chloride ions) diffuse into the crevice through electromigration, leading to an increased metal-chloride concentration. The pH within the crevice drops as a result of the metal-ion hydrolysis.

When the concentration of chlorides is sufficiently high and the pH is sufficiently low, the passive film is no longer able to maintain stability, and active corrosion results. This CCS theory relies on the accumulation of aggressive species within the crevice, and subsequent depassivation followed by active dissolution, as indicated by polarization curve a in **Figure 3**. Meanwhile, the boldly exposed surfaces remain in the passive state, as indicated by polarization curve c shown in **Figure 3**. The CCS theory predicts that the most severe crevice corrosion damage should occur in the deepest regions of the crevice since these would be the first areas to become deoxygenated because of the oxygen mass transport limitations. In some systems, however, crevice corrosion is observed at intermediate distances from the crevice mouth. Another limitation of the CCS model, as noted in the Oldfield and Sutton paper (1973), is that no consideration is given to the effect of the IR drop during the initiation stage.

### 2.03.2.3 IR Drop

The ohmic potential difference or the so-called IR drop theory for describing crevice corrosion was developed by Pickering.<sup>11,12</sup> The IR drop refers to the variation in potential between the crevice interior and the boldly exposed surfaces surrounding the crevice mouth. If the IR drop is sufficiently large, the potential in the crevice can drop below the value required to maintain a stable passive film, thereby initiating crevice corrosion through depassivation. The IR drop increases as the aspect ratio (i.e., length to depth ratio) or tightness of the crevice increases. The IR drop is also affected by other factors such as solution chemistry and conductivity, as well as the presence of other physical objects, such as hydrogen bubbles, solid corrosion products, and salt films that may further block the crevice.<sup>12</sup>

When the metal surfaces within the crevice become net anodic, the local corrosion potential typically becomes more active (i.e., more negative). With the relatively large boldly exposed surfaces supporting the cathodic reactions at more noble (i.e., more positive) potentials, it might be expected that the small surface area within the crevice region would be polarized to higher potentials where it would no longer be active. Due to large IR drops, however, the potential of the crevice region can be hundreds of millivolts lower than that of the boldly exposed surfaces.<sup>11,12</sup>

**Figure 3** Schematic of crevice corrosion. Net anodic reactions occur within the crevice environment while the boldly exposed surface is net cathodic. Three possible polarization behaviors are shown: (A) active dissolution within the crevice region, (B) active-passive behavior within the crevice region, and (C) passive behavior on the boldly exposed surface.

In metals and alloys that exhibit an active-to-passive transition in bulk environments, the boldly exposed surfaces are maintained in the passive region in aerated solutions, as indicated by polarization curve B in **Figure 3**. The large IR drop, however, can cause the local potential of the metal surfaces within the crevice to be less than the primary passivation potential, resulting in accelerated metal dissolution. The distance into the crevice where the interfacial potential reaches the primary pitting potential, is referred to as  $X_{\text{crit}}$ , and the critical IR drop to achieve this potential is called  $IR^*$  or  $\Delta\phi^*$ .<sup>11,12</sup> As the distance into the crevice increases, the resistance increases and the current decreases; consequently, the degree of crevice corrosion also decreases. The IR drop theory predicts the intermediate attack that is typically observed in many situations in which the metal or alloy undergoes an active-to-passive transition in the bulk environment, but it does not model the solution concentration process occurring in the crevice.

If the CCS and IR drop theories are combined, the behavior of metals and alloys that do not exhibit an active-to-passive transition in bulk solutions, but do show such behavior in lower pH solutions, can be explained. For instance, by applying both the CCS and the IR drop theories, the crevice corrosion behavior of Inconel 625 can be explained.<sup>13,14</sup>

Indeed, the majority of materials that are susceptible to crevice corrosion are passive in the bulk environment (e.g., stainless steels in aerated chloride environments) and do not normally exhibit an active-to-passive transition. Stewart and Kelly investigated the behavior of 300 series stainless steels taking into consideration the interaction of both the CCS model and the IR drop theory for initiation and propagation.<sup>1,15,16</sup> Their model considered conditions whereby an alloy was passive in the bulk environment, as shown in **Figure 3**, polarization curve c, but where crevice solution concentration and acidification must occur to allow an active-to-passive transition within the crevice, as shown in **Figure 3**, polarization curve b, which, in turn, results in crevice corrosion in the active region. With this approach, the Stewart and Kelly model correctly predicts the intermediate crevice-corrosion damage typically observed on many metals and alloys.

#### 2.03.2.4 Stabilization of Metastable Pits

Crevice corrosion occurs at potentials below the pitting potential in most environments. Similarly, metastable pitting occurs on stainless steel alloys at

potentials less than the pitting potential.<sup>2,17</sup> Stockert and Boehni<sup>18</sup> have suggested that crevice corrosion is initiated on stainless steels as a result of the occluded environment preventing the repassivation of metastable pits. Typically, repassivation of metastable pits occurs as a result of the pit's inability to maintain a critical solution concentration necessary for autocatalytic pit growth. The geometry of the occluded region prevents mass transport of metal-ion hydrolysis products generated from the metastable pitting, out of the crevice, which leads to an alteration of the crevice chemistry in a manner similar to the CCS model first proposed by Crolet and Defranoux<sup>7</sup> and Oldfield and Sutton.<sup>5,6</sup> Oldfield and Sutton observed that random metastable pits formed within the crevice in areas where mass transport was most limited. As exposure time increases, the density of metastable pitting events within the crevice increases; this is followed by pit coalescence as the density of the pits increases further. This coalescence of metastable pits is observed on electrode surfaces prior to crevice corrosion propagation. Other authors support Stockert and Boehni's contention.<sup>19,20</sup> For example, Laycock *et al.* hypothesized that crevice corrosion could be initiated by a random metastable pitting event occurring at a critical location within a crevice, where the metastable pits would then stabilize.

#### 2.03.2.5 Similarity to Pitting

Crevice corrosion and pitting corrosion are similar in many respects. The ranking of metal alloys for crevice corrosion and pitting corrosion are almost identical, and, therefore, it follows that the effect of alloying elements and the environmental effects on crevice corrosion and pitting are also similar.<sup>2</sup> One of the differences, however, between the two mechanisms is the initiation site for corrosion. In pitting corrosion, the initiation sites are, typically, heterogeneities in the metal or alloy surface (e.g., MnS inclusions in stainless steel or second phase particles in aluminum alloys) that are more susceptible than the metal or alloy matrix (e.g., MnS inclusions in stainless steel or second phase particles in aluminum alloys). In contrast, the initiation sites for crevice corrosion are generally defined by occluded regions as discussed previously, although pitting at surface heterogeneities, such as inclusions, has also been observed within crevices. While pitting generally occurs in halide containing solutions, crevice corrosion can also occur in nonhalide solutions, for example, nickel in sulfuric acid environments.<sup>2,17</sup> Also, the initiation mechanism is different for pitting

and crevice corrosion. Pitting is thought to be a random or stochastic process with respect to time and location, with metastable pits forming below the critical pitting potential, whereas crevice corrosion is generally considered a more deterministic process.<sup>2</sup>

Both pitting and crevice corrosion exhibit critical threshold potentials and temperatures. Typically, the critical crevice potential is lower than the critical pitting potential as the solution chemistry can change more rapidly in a crevice due to metal-ion hydrolysis and electromigration than in a pit on a boldly exposed surface. As a consequence, crevice corrosion usually initiates more readily than pitting. The critical crevice temperature (CCT) is usually lower than the critical pitting temperature (CPT) for many alloys for similar reasons.<sup>2</sup>

### **2.03.2.6 Variables Affecting Crevice Corrosion**

#### **2.03.2.6.1 Crevice geometry**

The crevice gap plays a major role in the development of the conditions required for crevice corrosion. Both the gap and the depth of the crevice control the mass transport (solution concentration, acidification, and deoxygenation) and potential gradients that develop within the crevice. In crevices with large gaps the mass transport of oxygen is relatively unaffected compared to bulk solutions, and crevice corrosion is unlikely. Narrow crevice gaps, however, create steep concentration gradients, which are more apt to initiate crevice corrosion closer to the crevice mouth. In addition, in narrow crevices the surface finishes on each side of the crevice become increasingly important. When the crevice surfaces are very close together the minimum crevice gap is dictated by the surface roughness. Large crevice gaps, however, are unaffected by surface roughness.

Various scaling factors are used to describe the effect of the crevice gap and depth on crevice corrosion; as the aspect ratio increases, mass transport gets more difficult and crevice corrosion becomes more likely. Additionally, studies have shown that large aspect ratios lead to crevice corrosion initiation closer to the mouth opening due to IR drop mechanisms.<sup>21</sup> To account for these effects, scaling laws are typically given in terms of the aspect ratio  $L/G$  or  $L^2/G$  where  $L$  is the depth at which crevice corrosion is first observed, and  $G$  is the crevice gap. Such scaling allows corrosion engineers and scientists to extrapolate crevice corrosion test results to other proposed design conditions.

#### **2.03.2.6.2 Solution chemistry**

For a given material, susceptibility to crevice corrosion and the rate at which it occurs are dependent on the environment to which it is exposed. Temperature plays an important role in a material's susceptibility to crevice corrosion. Below a critical temperature, a material is regarded as resistant to crevice corrosion, and corrosion rates are very low. Conversely, above this critical temperature, the corrosion rate increases sharply with increasing temperature. Additionally, one of the main natural crevice corrosion formers is biofilm growth. In specific temperature ranges, biofilms accelerate crevice corrosion by facilitating the cathodic reactions. Biofilms are less active above and below this temperature range leading to a reduced effect on the cathodic reactions, and therefore, lower crevice corrosion rates.

Solution chemistry plays an important role in the susceptibility of metals and alloys to crevice corrosion. Chloride-containing solutions are the most widely investigated and characterized environments in which crevice corrosion occurs on otherwise normally corrosion resistant materials.<sup>22,23</sup> Chloride ions facilitate crevice corrosion initiation and propagation. A critical concentration of chloride ions has been determined for many materials; below this critical concentration, crevice corrosion does not occur. Above this concentration, however, crevice corrosion is strongly dependent on concentration. As the concentration of chloride ions increases, the potential at which crevice corrosion initiates, decreases.<sup>24</sup> One explanation for this is that chloride-ion concentration plays a significant role in the mechanisms of pitting and metastable pitting. As the chloride ion concentration increases, the potential at which metastable pitting occurs decreases, as does the pitting potential. Metastable pits have been found on surfaces within crevices at the onset of crevice corrosion, and pit coalescence, at later stages.

The solution flow rate has been shown to affect the initiation and propagation phases of crevice corrosion differently. The initiation stages are inhibited by solution flow by enhancing the mass transport of oxygen to creviced regions.<sup>22,23</sup> Additionally, solution flow can help reduce the occurrence of crevice corrosion resulting from natural crevice formers by preventing sediment accumulation or attachment (e.g., biofilms or microorganisms).<sup>23</sup> Once crevice corrosion initiates, however, solution flow can increase the rate of crevice corrosion by increasing the rate-limiting cathodic reaction of oxygen reduction on the boldly exposed

surfaces outside the crevice. As the cathodic reaction increases, so the anodic dissolution reaction in the crevice must also increase.

### 2.03.2.6.3 Alloying

The alloy additions that impart resistance to pitting corrosion are for the most part the same as those that make alloys more resistant to crevice corrosion. One of the most widely investigated groups of alloys are the stainless steels. The additions of chromium, molybdenum, nitrogen, and nickel have a significant influence on the crevice corrosion resistance of many alloys. The crevice corrosion rate of austenitic stainless steels has been shown to decrease with increasing chromium additions in seawater.<sup>23</sup> The addition of chromium enhances the passivity of the oxide film, making it more resistant to breakdown. As with resistance to pitting, crevice corrosion resistance is enhanced by the addition of molybdenum. The addition of nickel has been shown to be beneficial to the crevice corrosion resistance of 2.5% Mo austenitic stainless steels, while it has shown very little effect for 6.5% Mo stainless steels. Molybdenum and nitrogen additions have been shown to have a synergistic effect. In alloys that contain molybdenum, nitrogen addition results in significant decreases in the crevice corrosion rate. Similar results are observed for ferritic stainless steels as for austenitic stainless steels.<sup>23</sup> Manganese sulfide inclusions have also been shown to influence the crevice corrosion resistance of austenitic stainless steels; they have been found to destabilize passive films, leading to an increased susceptibility to crevice corrosion.<sup>2,25–30</sup>

The pitting resistance of different stainless steel alloys is generally approximated from the alloy composition by means of the pitting resistance equivalence number (PREN) equation.<sup>23</sup> A typical PREN formula for stainless steels<sup>31</sup> is  $PREN = Cr + 3.3Mo + 30N$ , while, according to Roberge,<sup>32</sup> the most widely used formula for austenitic and duplex stainless steels is  $PREN = Cr + 3.3 (Mo + 0.5W) + xN$ , where  $x = 16$  for duplex stainless steel, and  $x = 30$  for austenitic alloys. This shows that increasing chromium, molybdenum, and nitrogen will increase the pitting and crevice corrosion resistance of a stainless steel. According to Grubb and DeBold,<sup>33</sup> the numerical value of the PREN is approximately equal to the critical crevice temperature (CCT) as measured in degrees Celsius in natural seawater or in ferric chloride solution. This can be seen by comparing the PREN formula with the formula for the CCT in degrees Celsius for stainless

steels, which is given by  $CCT = 2.5Cr + 7.6Mo + 31.9N - 41.0$ .<sup>34</sup> PREN and CCT data are presented for a number of alloys in 30 °C filtered seawater for 30 days in Table 1, which shows the limited equivalence between PREN and CCT.

High performance nickel alloys show improvements in crevice corrosion resistance similar to stainless steels in terms of alloying elements. Alloy C-276, which contains 8% molybdenum, has a relatively higher crevice corrosion resistance, when compared with alloys with lower molybdenum contents.

**Table 1** Crevice corrosion rankings in 30 °C filtered seawater for 30 days, with PREN<sup>a</sup> and CCT<sup>b</sup>

Alloy	UNS designation	Crevice corrosion resistance ranking	PREN	CCT (°C)

<sup>a</sup>Bond, A. P.; Dundas, A. J. *Mater. Perform.* **1984**, 23(7), 39.

<sup>b</sup>Roberge, P. R. *Handbook of Corrosion Engineering*, McGraw-Hill: New York, 1999; p 734.

Similarly, increases in chromium content lower the rate of crevice corrosion.<sup>13</sup>

Titanium and its alloys are, typically, very resistant to crevice corrosion; for instance, pure titanium (Ti-Grade 2) will not generally undergo crevice corrosion below 70 °C, regardless of the solution pH or chloride concentration. When the pH exceeds 10, pure titanium will not undergo crevice corrosion at any temperature.<sup>35</sup> Although titanium and its alloys have high resistance to crevice corrosion, small additions of alloying elements lead to a marked reduction in the rates of crevice corrosion.<sup>31</sup> The addition of noble alloying elements, such as platinum and palladium, as well as copper, significantly decreases the crevice corrosion rate of titanium alloys by providing additional cathodic reaction sites within the crevice. Increasing the number and area of cathodic reaction sites within the crevice allows for the reduction of hydrogen ions, preventing the large scale separation of anodic and cathodic reaction sites.<sup>31</sup>

### 2.03.3 Evaluation of Crevice Corrosion

Numerous tests have been developed to investigate and evaluate the crevice corrosion susceptibilities of metals and alloys. The reviews by Kearns and Kain describe many of the test methods.<sup>9,36–38</sup> In general, testing has been focused primarily on normally passive alloys, and in particular, it has been directed towards the identification and development of more corrosion resistant alloys for marine applications and certain process industries, such as the pulp and paper industry.

Of the many tests that have been developed, several broad classifications can be made based on the type of test, for example, field or *in situ* tests, as opposed to those conducted in the laboratory, and real-time tests versus accelerated tests. Another differentiation can be made between electrochemical and nonelectrochemical (e.g., simple immersion) tests, as well as those tests designed specifically to investigate initiation rather than propagation. Further classifications can be made according to the specific environment, the type of crevice former used, and the geometry of the specimen (e.g., flat sheet, cylindrical, etc.)

As is often the case with testing versus real-life experience, the occurrence or absence of crevice corrosion in a given test is no assurance that it will or will not occur under normal service conditions, either as one moves from the laboratory to the field, or as field process conditions change with time.

#### 2.03.3.1 Variables Affecting Crevice Corrosion Testing

In designing or selecting an appropriate test for evaluating crevice corrosion, a number of variables need to be taken into consideration:

- The metallurgical condition of the metal or alloy, including its composition and surface finish.
- The material used for the crevice former, including its surface finish. The nature of the crevice former can affect the crevice geometry, through relaxation of the crevice gap over time. If a metallic crevice former is used, then dissimilar metal corrosion may be an issue to consider.
- Crevice geometry, including the crevice gap, length or depth, and tightness. The geometry of the crevice can affect the initiation and propagation phases differently, and partly determine the crevice-to-barely-exposed surface area ratio.
- The bulk environment, including solution chemistry, temperature, and flow rate, all of which affect crevice corrosion and can be utilized to accelerate testing.

#### 2.03.3.2 Field or *In Situ* Tests

ASTM International standard G 4-01, Standard Guide for Conducting Corrosion Tests in Field Applications, provides general guidance for such tests, particularly with respect to surface preparation, specimen design, test-rack assembly, and post-test evaluation.<sup>39</sup> The standard mentions crevice corrosion and makes reference to ASTM standard G 78-01. The use of test racks to investigate *in situ* crevice corrosion provides little information regarding initiation and propagation rates.<sup>9,36</sup> However, this approach is effective for screening and ranking different alloys.<sup>40</sup>

#### 2.03.3.3 Laboratory Tests

##### 2.03.3.3.1 ASTM G 48-03, standard test methods for pitting and crevice corrosion resistance of stainless steels and related alloys by use of ferric chloride solution

ASTM standard G 48-03 lists several procedures to determine the pitting and crevice corrosion resistance of stainless steels and other nickel-based corrosion-resistant alloys, when exposed to oxidizing chloride environments.<sup>41</sup> This test describes four procedures, identified as methods A, B, C, and D. Method

A is a ferric chloride pitting test, and Method C is a test developed for determining the critical pitting temperature; therefore, these two methods will not be discussed.

Method B is a ferric chloride test that was developed by Streicher for determining both the pitting and crevice corrosion resistance of iron- and nickel-based alloys.<sup>42</sup> In this test, the crevices are formed by two plastic blocks held against the specimen faces. The maximum depth or mass loss is measured after immersion for a specified time. The recommended temperatures and duration are 23 or 50 °C, and 72 h, respectively.

Method D is used to rank alloys with respect to the minimum critical crevice temperature to cause initiation of crevice corrosion in 72 h, and is similar to the MTI-2 test developed by Treseder.<sup>43</sup> The critical crevice temperature is defined by ASTM G 48 as the minimum temperature to produce crevice attack to a depth of at least 0.025 mm on the surface of the specimen beneath the crevice former in 72 h.

These accelerated test methods (A–D) were designed to minimize corrosion initiation times compared with most natural environments. The rationale for using ferric chloride solutions is that similar solutions are expected to develop within a pit or crevice site.<sup>44</sup> (While this may have been the original rationale, it is not certain why ferric chloride works (rather than any other chloride solution). Rather ferric ion reduction provides a powerful cathodic reaction, leading to a very positive potential that ensures that crevice corrosion will occur if the potential is above the CCT.) The relative performance of alloys in ferric chloride solution tests has been correlated to performance in certain real environments, such as natural seawater at ambient temperature<sup>45</sup> and strongly oxidizing, low pH, chloride-containing environments.<sup>10</sup> Several exceptions to these correlations, however, have been reported.<sup>46,47</sup> This test method notes that surface preparation can significantly influence results. For instance, grinding or pickling of stainless steel surfaces can destroy the passive layer; however, a 24-h air-passivation after grinding or pickling will minimize these differences.

#### **2.03.3.3.2 ASTM G 78-01, standard guide for crevice corrosion testing of iron-base and nickel-base stainless alloys in seawater and other chloride-containing aqueous environments**

ASTM G 78-01 was developed to measure the crevice corrosion resistance of iron- and nickel-based

alloys to chloride containing solutions for a specified time period.<sup>48</sup> This standard recommends a 30-day exposure. The sample surface is occluded with two multiple-gap plastic washers, or so-called multiple crevice assemblies (MCA), that are firmly pressed against both surfaces. This test was developed in the 1970s and is often cited in the literature. Tests are performed on triplicate specimens to allow for statistical analysis, with the crevice formers tightened using a calibrated torque wrench. Crevice initiation and propagation are addressed by the number of sites initiated, and the maximum depth of attack, respectively. Round-robin testing by both NACE T-5H-6 and ASTM G 1.09 task groups report results illustrating the variability of these types of test. The use of multiple-crevice assemblies can be useful for the ranking of alloys, as well as for investigating the effect of other variables; however, multiple-crevice assemblies should not be used for predicting alloy performance in other conditions.

#### **2.03.3.3.3 ASTM F 746-87 (Reapproved 1999), standard test method for pitting or crevice corrosion of metallic surgical implant materials**

ASTM F 746 can be used to evaluate the localized corrosion resistance of alloys for implantable medical devices and surgical instruments.<sup>49</sup> It is a modified version of a test developed by Syrett,<sup>50</sup> and is used as a screening test to rank alloys.

A cylindrical sample of the alloy to be tested is fitted with an inert tapered collar and then immersed in a phosphate-buffered saline (PBS) solution at 37 °C. After stabilization over 1 h, the sample is polarized to a potential much more noble than its rest potential, typically 0.8 V (SCE), in order to stimulate localized corrosion – either pitting or crevice corrosion. The onset of localized corrosion is evident as a rapid increase in the current. If localized corrosion cannot be stimulated, then, after 15 min, the test is terminated. If localized corrosion is stimulated, however, the potential is immediately decreased to the first of several preselected potentials (usually the rest potential plus 0.05 V), and the current is monitored to see whether the sample repassivates, or continues to corrode. If the sample does not repassivate after 15 min, the test is terminated. If the sample does repassivate, the stimulation step is repeated, followed by the next repassivation step. The critical potential for localized corrosion is defined as the most noble preselected potential at which repassivation occurs. Post-test examination of the sample establishes

whether the localized corrosion resulted from pitting of the exposed surface, or from crevice corrosion in the tapered collar.

**2.03.3.3.4 ASTM F 2129-06, standard test method for conducting cyclic potentiodynamic polarization measurements to determine the corrosion susceptibility of small implant devices**

ASTM F 2129 was developed to evaluate the localized corrosion resistance of medical implants in their finished condition.<sup>51</sup> The method can, however, also be used for screening alloys and evaluating component parts of implants. Implants (or alloy components) are immersed in PBS at 37°C for up to 1 h to stabilize at the so-called rest potential ( $E_r$ ) or open circuit potential, after which the potential of the sample is increased slowly (0.167 or 1 mV s<sup>-1</sup>) in a positive (noble) direction. The breakdown potential ( $E_b$ ) at which localized corrosion occurs is evident by a rapid increase in the current and, typically for stainless steels or Nitinol in PBS, can be observed by the appearance of a cloud of corrosion product forming around the breakdown location. If no breakdown occurs before a preset vertex potential is reached, usually 0.8 or 1 V (SCE), then the test can be terminated. If breakdown does occur, and the test is designed to be destructive, then the potential sweep is reversed and monitored for repassivation at the so-called protection or repassivation potential ( $E_p$ ). There remains, however, some controversy among researchers over how to interpret the data obtained from this test. One approach is to consider the gap between the breakdown and rest potentials (i.e.,  $E_b - E_r$ ). This gap provides a measure of the pitting corrosion resistance, whereby, the greater this gap, the greater the resistance to pitting corrosion. Although not universally accepted by researchers, this is a commonly accepted parameter for the ranking of different alloys or material processing.<sup>52–56</sup> Similarly, the parameter  $E_p - E_r$  is sometimes used as a measure of crevice corrosion resistance. This last parameter, however, is very dependent upon the amount of pitting or crevice corrosion that occurs before the potential scan is reversed.<sup>57</sup> An alternative approach for finished devices is to consider the parameter  $E_b - E_r$  as a measure of localized corrosion resistance, together with a posttest microscopic examination to determine whether breakdown occurred because of pitting or crevice corrosion.

ASTM G 61-86, Standard Test Method for Conducting Cyclic Potentiodynamic Polarization Measurements for Localized Corrosion Susceptibility of

Iron-, Nickel-, or Cobalt-Based Alloys, is similar to ASTM F 2129 with the exception that the test is performed at 25°C in 3.5% sodium chloride solution.<sup>58</sup>

**2.03.3.3.5 Remote crevice assemblies**

The use of remote crevice assemblies is an electrochemical approach that allows for the evaluation of both the initiation and propagation phases of crevice corrosion.<sup>8,59–61</sup> This approach entails the physical separation of the anode (crevice) and the cathode (boldly exposed surface) which are electrically connected via a zero-resistance ammeter; this, therefore, permits the measurement of the current flow between the anode and the cathode. Plotting the current versus the time provides information regarding initiation times, as well as propagation rates (based on the total charge passed), and the reproducibility of results is reportedly good.<sup>9</sup>

## **2.03.4 Practical Design Aspects**

As described above, crevice corrosion occurs in both fabricated and natural crevice regions. In both cases, occluded regions formed by the close contact between a metal surface and a nonmetal crevice former or a second metal surface can lead to accelerated corrosion attack in these regions. In order to prevent crevice corrosion from occurring, occluded regions and sharp inside corners should be avoided, wherever possible.<sup>62,63</sup> When materials are joined by rivets, continuous welding, or soldering, sealants should be used to prevent water uptake into occluded regions. When occluded regions cannot be avoided, decreasing the aspect ratio between the crevice depth and crevice gap can lessen the severity of crevice corrosion damage by reducing the steepness of concentration and potential gradients within the crevice. Metal-to-nonmetal crevices (e.g., gaskets) should be avoided because the crevice gap is typically much less than metal-to-metal crevices; this is because the nonmetal crevice former can conform to the metal surface resulting in tighter crevice geometries.<sup>62,63</sup> Metal-to-nonmetal crevices are typically designed to prevent water uptake; however, there is a fine line between being tight enough to prevent water uptake, and tight enough to facilitate capillary action, leading to severe crevice corrosion. Crevice corrosion can also be mitigated by careful material selection or processing. Materials that have a higher crevice corrosion resistance can be used as an overlay

in areas susceptible to crevice corrosion, to minimize damage. Materials with higher critical crevice temperatures or potentials, or generally higher PREN materials, tend to be more resistant to crevice corrosion. The ranking of crevice corrosion resistance for various stainless steels and nickel based alloys in seawater, along with PREN<sup>64</sup> and CCT<sup>32</sup> values, is given in [Table 1](#).

Materials can also be processed to help avoid crevice corrosion. Metal surfaces outside crevice regions can be painted to prevent cathodic reactions taking place, effectively reducing the area ratio between the anode and cathode regions, thus reducing the rate of crevice corrosion attack.

Additionally, processes can be designed to help prevent crevice corrosion. Natural crevices, such as precipitates and deposits, can be avoided by adding filtration systems to industrial process lines early in the process, to prevent deposits in stagnant regions of the process line.

Solution phase inhibitors or supporting electrolytes can also be added to processing lines to either inhibit corrosion directly, or change solution conductivity to minimize ohmic potential effects, or disrupt ion migration into occluded regions.

### 2.03.5 Industry Specific Examples of Crevice Corrosion

Crevice corrosion is a common form of corrosion that affects a wide range of materials used in almost all industries. Metal-to-metal and metal-to-nonmetal crevices can lead to crevice corrosion in a wide variety of typical designs used for consumer and industrial products. Metal-to-metal crevices typically occur between strands in wire rope, around incomplete fusion welds in pipes and plates (see [Figure 4](#)), under o-rings and gaskets, in tube-to-tube sheet connections, in threaded connectors, and in a wide variety of other industrially-used geometries (see [Figure 5](#)).<sup>22</sup> Nonmetal-to-metal crevices can occur as a result of o-ring seals, gasket-to-flange joints, tape-coatings, barnacles on metallic surfaces, valve steam packing, dirt, sand, or mud deposits. This section will review how crevice corrosion affects material selection and mechanical design in a few exemplar industries.

#### 2.03.5.1 Medical Devices and Implants

Implantable medical devices are often used in situations where crevices are likely or unavoidable; for

**Figure 4** Example of crevice in welded structure.

**Figure 5** Example of crevice in welded structure.

instance, where the device is held against tissue or bone, where biofilms develop on the surface, or where two component parts of the device come together, such as screws in bone plates, or the crevice between a tapered stem and ball in a total hip replacement. For this reason, medical devices are required to possess long-term resistance to crevice corrosion during their expected service lifetimes. Common biomedical alloys used for long-term implants are stainless steels, cobalt–chromium–molybdenum alloys (including MP35N and Elgiloy), and titanium alloys. These alloys get their corrosion resistance from the presence of a thin passive film that is generally resistant to uniform corrosion, as well as pitting and crevice corrosion in the warm saline environment of the human body. The pH in the body is maintained at a relatively constant value of 7.4 by phosphate and carbonate buffering, under normal conditions. After surgery, however, the pH at the implant site may range from 5.5 to 9.0, as a result of immunological responses or infections.<sup>65</sup> In the case of a hematoma, the pH can remain at 5.5 for several days.<sup>66</sup> When implant crevice corrosion occurs, the pH may drop to 1 or even lower.<sup>67</sup>

The localized-corrosion resistance of long-term implants is important not only with respect to the maintenance of the mechanical and structural integrity of the implant, but also with respect to the rate at which leachable substances, such as nickel and chromium ions, are released into the body. The release of leachable substances, albeit at very low rates, can elicit an immunological response. This response can vary from person to person and can determine the difference between success and failure of the implant. An example is the corrosion and wear around orthopedic and dental implants that can cause metallosis of the surrounding tissue, and loosening of the implant at the fixation site.<sup>68–71</sup> Although commercial metallic biomaterials are generally corrosion-resistant, there has always been a concern that trace metal ions may be released into the human body because of pitting or crevice corrosion.

Titanium alloys, such as Ti Gr2 and Ti–6Al–4V, are generally ranked as having the greatest resistance to corrosion in saline solutions and are considered resistant to pitting up to the maximum normally-investigated potentials used for testing biomedical implant materials (i.e., 0.8 V SCE).<sup>51</sup> Titanium and its alloys typically show either negative hysteresis or no hysteresis in potentiodynamic polarization tests (i.e., current density falling off as rapidly or more rapidly on the reverse scan than on the forward scan), indicating that passive film growth is enhanced with increasing potential. Consequently, materials exhibiting no hysteresis or negative hysteresis are considered immune to pitting and crevice corrosion.<sup>51,65</sup> Nevertheless, titanium alloys can, under certain *in vivo* conditions such as fretting, show signs of pitting and crevice corrosion as discussed below.<sup>72</sup>

The corrosion resistance of Nitinol (or NiTi), which has an approximately equal nickel and titanium content, is not considered as great as that of titanium or other titanium alloys, such as Ti Gr2 or Ti–6Al–4V. As it exhibits superelastic and shape memory behavior, however, Nitinol is used extensively as an alloy for implantable medical devices, particularly for devices that are deployed endovascularly. There have been some reports that Nitinol will experience *in vivo* breakdown of the passive film, and subsequent localized corrosion. These reports of pitting or crevice corrosion observed on explants,<sup>73–76</sup> however, appear to have been a result of the explants being exposed to decontamination solutions, such as bleach, rather than as a result of actual *in vivo* corrosion.<sup>77–79</sup> Jacobs *et al.* examined Nitinol explants that had been implanted

for over 10 years, and that had not been decontaminated with bleach, and found no significant pitting or crevice corrosion.<sup>80</sup> Guidoin *et al.* examined Nitinol stents (with a radiopaque platinum coil wrapped around the Nitinol wire to make the device more visible during X-ray radiography) which they disinfected with bleach, and found little corrosion, except at the crevice between the coil and the Nitinol wire.<sup>73</sup>

The ASTM F 75 specification cobalt–chromium–molybdenum alloys, such as MP35N and Elgiloy, do not exhibit a hysteresis loop in their cyclic polarization curves and are generally thought to be resistant to pitting and crevice corrosion in physiological environments. These alloys exhibit electrochemical behavior in the passive range that differs from that of other biomedical alloys. In particular, their cyclic potentiodynamic polarization curves typically exhibit an increase in current at potentials of about 0.4 V SCE, and perhaps another at about 0.7 V SCE, but they do not show evidence of localized corrosion.<sup>81</sup> The first increase is thought to be associated with a solid-state oxidation reaction involving the conversion of Co(II) to Co(III). The second increase appears to be associated with transpassive dissolution that results in the release of chromium and nickel ions. The transpassive dissolution observed on cobalt–chromium–molybdenum alloys is a general dissolution type of corrosion and does not generally result in crevice or pitting corrosion. These alloys have exhibited pitting and crevice corrosion under certain *in vivo* conditions, however, and these will be discussed below.

Although 316L and ASTM F 138 (ISO 5832-1) specification stainless steels are alloys used for medical implants, they are susceptible to crevice corrosion in human body fluids.<sup>23</sup> Such crevice corrosion can release metallic ions into the tissues surrounding the implants, causing local irritations or systemic effects. The potential for crevice corrosion of 316L stainless steel *in vivo* is not surprising, since 316L has a CCT below body temperature (see [Table 1](#)).

According to Bai and Gilbert,<sup>65</sup> researchers found that 91% of 316 stainless steel multicomponent explants had undergone visible corrosion, and that crevice corrosion was the primary type of attack.<sup>82</sup> Bai and Gilbert<sup>65</sup> also report the findings of a retrieval study<sup>83</sup> in which it was found that 89% of the plates and 88% of the screws of 250 stainless steel internal fixation devices showed evidence of pitting and crevice corrosion. The environment within the crevices formed between plates and screws of orthopedic devices can be altered from that of the normal *in vivo* environment, such that values ranging from

pH 5 to 7, less than 8–110 mmHg for  $pO_2$ , and less than 10–300 mmHg for  $pCO_2$  can be formed.<sup>84</sup>

Some of this corrosion is a reflection of the quality of the stainless steel used in those pioneering days; it had higher carbon and inclusion content than the medical-grade materials used nowadays. Since that time, there have been significant changes in the composition specified for medical grade 316L (ASTM F 138), which now has a specified minimum PREN of 26.<sup>85–87</sup> The first improvement came with the development of AISI 316L, which is still widely used for plates, screws, and nails in orthopedic surgery. As there were continuing reports of *in vivo* stainless steel corrosion, a new type of stainless steel was introduced in the mid-1980s. This alloy has higher chromium and manganese than 316L, and 0.5% nitrogen is added for increased corrosion resistance.<sup>87</sup>

In 1972, Cohen and Wulff described a cobalt-alloy plate and screws that had been removed from a patient; the persistent pain that the patient experienced appeared to be associated with corrosion.<sup>88</sup> The plates and screws were found to have failed because of crevice corrosion between the plate and bone. The plate composition was similar to Stellite 25 (Co–20Cr–15W–10Ni) and the screw composition was similar to Stellite 21 (Co–27Cr–5.5Mo). Cohen and Wulff noted that the corrosion was associated with the plate and not the screws. Reports of corrosion problems and adverse tissue response with Stellite alloys, however, have been extremely rare.<sup>89</sup>

Brown *et al.* discussed crevice corrosion in stainless steel bone plates and screws<sup>69</sup> and modular hip implants.<sup>68</sup> Crevice corrosion tests with bone plates and screws exposed for up to 1 year showed that crevice corrosion does not occur in isotonic saline solutions (0.9% NaCl) for periods of up to 1 year, but can occur in hypertonic saline solutions (7.2% NaCl). Brown *et al.* also observed corrosion of bone plates and screws that had been fixed to the tibia of sheep, but concluded that this corrosion, as well as the corrosion reported on clinically retrieved implants, was initiated by fretting corrosion, which predisposes the contact area to crevice corrosion attack.

Multiple-component systems used in orthopedic surgery provide flexibility in choosing the optimal implant, but introduce the possibility of crevice corrosion that could limit the implant's longevity, either because of unfavorable tissue response to corrosion products or device failure.<sup>68</sup> Based on their high *in vivo* corrosion resistance, both titanium and cobalt–chromium alloys are often used for total

joint replacements.<sup>90</sup> Because these joints are articulating, the wear resistance of the alloys is also important. Compared with cobalt–chromium alloys, titanium alloys have relatively poor wear properties, and therefore, the cobalt-base alloys are more commonly used for the articulating components of total joint replacements.<sup>90</sup> Since the 1980s, the modular joint, in which the femoral-head component is fabricated from a cobalt-base alloy and the stem from extra-low interstitial (ELI) Ti–6Al–4V alloy, has gained popularity, particularly for the artificial hip. The galvanic couple created by this arrangement was not considered a problem, as both alloys were passive. By the early 1990s, however, there had been reports of corrosion observed on these implants and Brown *et al.*<sup>68–69</sup> attributed these instances to a fretting-assisted crevice-corrosion mechanism.

The work by Brown *et al.*, in 1995 on 79 retrieved tapered modular hip implants indicated similar behavior, that is, the effect of fretting on crevice corrosion initiation. This work suggested that design changes that decreased the propensity for fretting also reduced the chance of crevice corrosion.<sup>68</sup> In addition, Gilbert *et al.* examined 148 total modular hip implants with mixed (Ti–Al–4V)/Co–Cr and Co–Cr/Co–Cr stem and head combinations,<sup>72</sup> and reported that both combinations showed about the same amount of corrosion in the creviced region between the tapered stem and head. They concluded that galvanic effects were not significant, but that crevice corrosion could occur in cobalt–chromium alloys in fretting and wear situations. Cobalt–chromium–molybdenum alloys, therefore, appear to be resistant to pitting and crevice corrosion in the unloaded condition, but are susceptible to deterioration in the presence of mechanical loads. This form of crevice corrosion has been described by Gilbert and Jacobs as mechanically-assisted crevice corrosion.<sup>67</sup>

As reported by Thomas *et al.*, cemented titanium stems in hip arthroplasty have experienced proximal cement–stem debonding, which can result in a crevice, and early failure.<sup>91</sup> This was well publicized with the 3M Capital hip implant failures. Thomas *et al.* discussed their examination of a series of 12 cemented titanium Furlong Straight Stems that required revision at a mean implant time of 78 months, as a result of thigh pain. They reported that the stems were severely corroded in a pattern that was typical of crevice corrosion. Their conclusion was that the combination of a titanium stem and cement appears to facilitate fretting-induced crevice corrosion for an otherwise crevice corrosion resistant material.

Crevice corrosion has also been found on tibial plateau leveling osteotomy (TPLO) plates and associated bone screws that had been implanted in dogs for ~3 years.<sup>92</sup> It was reported that surface irregularities and porosity of TPLO plates from the casting process provided crevice corrosion initiation sites in the occluded region between the plates and screws.

Crevice corrosion has also been seen on spinal surgery hardware. Tezer *et al.* noted that crevice and fretting corrosion can occur at the junctions of rod-screw, rod-hook, transverse-connector rods, and other connector rods in modular spinal implants.<sup>93</sup> They recommended using alloys with better corrosion resistance to inhibit crevice and fretting corrosion. Modular-spine implants are used to aid fusion, but fretting and corrosion can occur between modular components. Kirkpatrick *et al.* examined the corrosion on 47 explanted spinal implants that were manufactured by a variety of companies.<sup>94</sup> They observed that the stainless steel implants exhibited a range of corrosion, from minor to severe damage, that was consistent with previously observed mechanically-assisted crevice corrosion. Titanium-alloy implants, however, showed no significant corrosion. The single cobalt-alloy explant showed no evidence of corrosion.

#### **2.03.5.1.1 Dental crevice corrosion**

With dental implants there is the possibility of microbiologically-influenced corrosion (MIC) affecting crevice corrosion in the creviced region between the dental implant and the gingival epithelium.<sup>71</sup> According to Megremis and Carey, seepage of oral secretions into the crevices created between the restoration and the tooth can lead to microorganism invasion, generation of acidic conditions, the operation of differential aeration cells, and crevice corrosion.<sup>95</sup> The creation of crevice conditions in amalgams can increase acidity to well below a pH of 4. To enhance the crevice corrosion resistance of dental surgical materials, the German Federal Health Department recommended minimum amounts of chromium and molybdenum of 20% and 4%, respectively.<sup>95</sup> In 2006, Wylie *et al.* performed electrochemical testing in artificial saliva at different pHs, on two nickel-based dental casting alloys, before and after porcelain-firing heat treatments.<sup>96</sup> Crevice corrosion was observed on alloys exposed to pH 2.5 saliva. They noted, not surprisingly, that the presence of crevices and lower chromium-content nickel-base alloys could lead to crevice corrosion in dental casting alloys, but this could be avoided by an increase in the chromium content of the alloy.

#### **2.03.5.1.2 Nickel-free alloys**

Many medical implants contain nickel, which has led to concerns regarding nickel toxicology and its effect on the implants' biological performance.<sup>70,97–98</sup> As a result, there have been several recent efforts to develop nickel-free biomedical alloys.<sup>97</sup> Along these lines, Reclaru *et al.* analyzed the crevice corrosion behavior and the cation release of five nominally nickel-free austenitic steels in artificial sweat and bone plasma.<sup>98</sup> Generally, the amount of cation release was substantially higher in the artificial sweat solution than in the bone plasma under creviced conditions.<sup>99</sup>

### **2.03.5.2 Chemical and Power Plants**

#### **2.03.5.2.1 Boiler and steam generators**

It has been estimated that the second most common type of tube failure in fire-tube boilers is concentration-cell corrosion, frequently referred to as crevice corrosion, due to the build-up of iron oxide sediment or scale.<sup>100</sup> On waterside fire-tubes, corrosion occurs beneath deposits that foul the surface and become anodic relative to the periphery of the deposits. According to Esmacher *et al.*,<sup>100</sup> crevice corrosion also occurs at tube-to-tubesheet roll joints, particularly if high thermal stresses cause flexing at the joint, and crack protective oxides or allow water ingress into the crevice.

#### **2.03.5.2.2 Heat exchangers and condensers**

Heat exchangers and condensers are widely used in the power generation and chemical processing industry. Almost all heat exchangers have crevices at the tube-sheet and the tube support-plate locations. For example, in the nuclear power industry, crevice corrosion has resulted in costly tube denting (see [Section 2.03.5.2.3](#)), as well as intergranular attack (IGA), and stress corrosion cracking (SCC) of Inconel 600 (Alloy 600) in tube-sheet and tube support-plate crevices.<sup>101</sup>

Dissimilar metal crevices (DMC) are common features of heat exchangers and condensers. Tube-to-tube sheet joints frequently contain crevices and dissimilar tube and tubesheet materials. Work by Kearns<sup>102</sup> and Maurer<sup>103</sup> on DMC in seawater have shown that the more corrosion resistant materials in a DMC can be made to corrode as a result of the corrosion products from the less resistant alloys.

#### **2.03.5.2.3 Pressurized-water reactors (PWR) and boiling-water reactors (BWR)**

Crevices in oxidizing environments, or boiling at heat-transfer surfaces, can result in a variety of crevice corrosion problems for both BWR and PWR

operations. According to Ford *et al.*, in most BWR designs, the coolant purity approaches that of theoretically pure water (i.e., a room-temperature conductivity of  $0.055 \mu\text{S cm}^{-1}$ ), with dissolved chloride and sulfate ion concentrations below 5 ppb, in order to help prevent the concentration of impurities in crevices.<sup>104</sup>

One of the main differences between the PWR and BWR designs is that a PWR has a steam generator that isolates the primary water (i.e., water heated by the reactor core under pressure) from the secondary water that is boiled to make the steam that runs the turbines. A serious crevice corrosion problem appeared in PWRs during the mid-1970s.<sup>105</sup> The phenomenon became known as denting, and it occurred in Inconel 600 tubing because of corrosion in the crevices between the tubes and the carbon steel support plates or tube sheets. In the crevices between the Inconel 600 steam generator tubes and the steel tube-sheets, tube support-plates, and sludge deposits, where water circulation is restricted by geometry and deposits, boiling can concentrate the very low levels of impurities in the secondary water to very high concentrations. This is known as hideout. The concentration of impurities in crevices, under heat transfer conditions, can be 20 000 times that present in the bulk secondary water.<sup>105,106</sup> Denting can restrict primary water flow and result in SCC and IGA, which may result in primary water leaking into the secondary side. Tube damage from hideout, such as wastage, pitting, and denting has been largely eliminated by appropriate management of secondary water chemistry, which includes reducing condenser impurity in-leakage, reducing air in-leakage, using make-up water of higher purity, using boric acid to inhibit acidic chloride attack, and using condensate polishers to purify the feedwater. Newer steam generator designs have used Inconel 690 (Alloy 690) or Incoloy 800 (Alloy 800) that are more corrosion resistant to the highly concentrated environments that can develop in the tube-sheet and tube support-plate crevices, and under sludge piles.<sup>105</sup>

### 2.03.5.3 Aerospace

Most commercial aircraft utilize aluminum alloys for their airframe structures, which are susceptible to pitting, crevice corrosion, exfoliation, and environment-assisted cracking under normal operating conditions.<sup>107–109</sup> Crevice corrosion on aircraft can occur at unsealed joints or at joints where the fillet seal has broken, on fuselage structures held in intimate contact with wet insulation blankets, and on aluminum and

stainless steel tubing under rubber clamps.<sup>107</sup> As described by Inman *et al.*, crevice corrosion and subsequent fatigue cracking of airframe structures can occur and lead to loss of life. They list a number of examples whereby crevice corrosion along riveted structures, which are difficult to inspect, led to fatigue cracking and subsequent failure of sections of the fuselage.<sup>108</sup> For instance, in 1981, the failure of a large portion of the fuselage of a commercial aircraft in Taiwan was attributed to undetected fuselage-skin corrosion that led to fatigue cracking. Another incident in Hawaii in 1988 revealed that fatigue cracking can occur in corroded fuselage structures.<sup>108</sup> Due to its nature, crevice corrosion in aircraft can be difficult to detect until it exceeds the limits allowed by design. As described by Inman *et al.*, moisture is drawn into crevices during normal service, and pollutant gases can dissolve in the water to form corrosive solutions which attack the protective oxide layer. Aircraft operating in marine environments have to contend with additional chloride ion ingress. Also, routine maintenance and cleaning procedures, such as washing and cleaning, can contribute to crevice corrosion.

According to Sankaran *et al.*, crevice corrosion can lead to severe intergranular and exfoliation corrosion, which, in turn, can lead to increased stress and crack growth rates due to the volumetric increase of corrosion products within creviced regions.<sup>110</sup> Faying-surface sealants, such as polysulfide sealants, have dramatically reduced the crevice corrosion of fuselage lap and similar aircraft joints.<sup>107</sup>

### 2.03.5.4 Nuclear Waste Isolation

High level nuclear waste, such as that resulting from spent nuclear fuel from commercial nuclear reactors used for power generation, needs to be isolated from the environment for 1000–10 000 years or longer.<sup>111,112</sup> Corrosion of the containment materials is considered to be the principal mode of degradation that will limit the lifetime of the waste package.<sup>113</sup> As crevice corrosion is thought to be a part of the limiting lifetime of these containment systems, much of the research on crevice corrosion in the last ten years has been devoted to a better understanding of crevice corrosion mechanisms in this highly engineered containment system.<sup>112</sup> With the proposed repository designs, crevices could be formed between the waste package and the emplacement pallet, by the deposition of mineral precipitates, corrosion products, dust, or by contact with rocks, and the drip shield or ground support materials.<sup>113</sup>

A common approach taken by many nations is to bury the waste underground in corrosion resistant containers. Early work at Yucca Mountain in Nevada, a potential repository site in the United States, initially focused on austenitic stainless steels as the container material<sup>112</sup>; however, this material selection has evolved over the years as the design requirements have increased. Originally, 304 stainless steel was specified as the container material, but as the corrosion resistance requirements increased, first Alloy 825, then Alloy 625, and finally Alloy 22, were selected. Alloy 22, a Ni–22Cr–13Mo–4Fe–3W alloy, was selected in order to have the highest resistance to localized corrosion phenomena, such as stress corrosion cracking, pitting, and crevice corrosion.<sup>112–115</sup> Since 1998, the waste-package design for the high-level waste repository at Yucca Mountain has specified a double-walled cylindrical container with the outer container made from Alloy 22, to resist corrosion, and an inner container made of Type 316 nuclear-grade stainless steel to provide strength and radiation shielding.<sup>112,113</sup> The container will be covered by a Ti Gr7 drip shield to guard against rock fall and prevent contact with water seepage during the first few hundred years.<sup>112</sup> Alloy 22 is extremely resistant to localized corrosion as a result of the formation of a 5–6-nm thick, chromium-rich oxide film. The general corrosion rate of Alloy 22 in acidic to alkaline solutions is expected to be well below  $0.1 \text{ mm year}^{-1}$  ( $0.004 \text{ mil year}^{-1}$ ), and therefore, the life of the containers for Yucca Mountain should not be limited by passive dissolution.<sup>112</sup>

Although the United States is considering burial in unsaturated formations (i.e., above the water table), and will therefore have to consider oxidizing redox potentials, it is unlikely that pitting corrosion will be life limiting, as it is unlikely that in this environment (hot concentrated groundwater), a sufficiently high electrochemical potential would be developed to initiate pits on the exposed surface of Alloy 22.<sup>112</sup>

As described by Rebak and McCright,  $E_{\text{crit}}$  is considered the potential above which localized corrosion could occur. The margin of safety against localized corrosion, therefore, will be the value of  $\Delta E$ , where  $\Delta E$  is the difference between  $E_{\text{crit}}$  and the uniform or passive corrosion rate,  $E_{\text{corr}}$  (i.e.,  $\Delta E = E_{\text{crit}} - E_{\text{corr}}$ ).<sup>112</sup> As the value of  $\Delta E$  increases, so does the margin of safety for localized corrosion.  $E_{\text{corr}}$  and  $E_{\text{crit}}$  both depend on the surface condition of the alloy, the environment, and the ambient temperature. Critical temperatures for pitting and crevice corrosion have been measured, and among the highest are those for nickel alloys.

Reassuringly, He and Dunn's work on crevice corrosion propagation indicate that although crevice corrosion of Alloy 22 is possible under some environmental conditions which may develop on the repository waste containers, the maximum penetration depth of localized attack is significantly less than the outer-container wall thickness, even under the aggressive environmental conditions used in their laboratory tests.<sup>113</sup>

### 2.03.5.5 Underground Structures

Most buried or submerged steel structures, such as pipelines and underground storage tanks, are painted or coated and cathodically protected to protect them from corrosion. If the coating becomes damaged or blistered, crevices can form underneath the protective coating and lead to crevice corrosion.<sup>116–118</sup> To compound the problem, cathodic protection may not be able to penetrate into the crevices formed by disbonded coatings. This so-called shielding is believed to be more severe for certain types of coating (e.g., polyolefin tape) and low conductivity groundwater.<sup>119</sup> Li *et al.*<sup>118</sup> have shown that the steel surface in freshly formed crevices under cathodic protection in dilute chloride environments may not immediately achieve the required protection potential of less than  $-0.850 \text{ V}$  (Cu/CuSO<sub>4</sub>). They have shown, however, that the crevice will become more alkaline as the cathodic reaction consumes the oxygen and forms hydroxide. The hydroxide ions then attract chloride ions into the crevice to maintain charge balance, which, in turn, increases the conductivity within the crevice, allowing protection potentials to be achieved.

It is important to realize that the foregoing description of corrosion within crevices as a result of damaged coatings should not be taken to imply either that carbon steels are susceptible to conventional crevice corrosion in neutral groundwaters or similar near-neutral solutions, or that crevice corrosion can occur on a steel structure that is cathodically protected. Under these conditions, corrosion does not occur by a conventional crevice corrosion mechanism, as the external potential is more negative than the corrosion potential, and therefore, the anodic reaction under the coating cannot be balanced by the external cathodic reaction. Instead, the corrosion derives from the fact that polymeric coatings are much more permeable to oxygen than to ions, and hence oxygen can penetrate the coating while the cathodic protection current cannot. As a result, the steel under the coating corrodes by a localized or general corrosion

mechanism, controlled by the rate of oxygen permeation through the coating. Similarly, a metal-metal crevice in a carbon steel structure will only suffer from crevice corrosion by the conventional mechanism when the external surface is passive, for example, in alkaline solutions. In neutral or acid solutions, such as acidic groundwaters and seawater, where the steel undergoes active corrosion, some iron dissolution will initially occur in the crevice, but this will quickly raise the ferrous ion concentration to such a level that either the  $\text{Fe}/\text{Fe}^{2+}$  reaction reaches equilibrium or the precipitation of ferrous oxides or hydroxides blocks the crevice and stifles the corrosion. When the external surface is subject to cathodic protection this simply reinforces this tendency, and the steel in the crevice will normally passivate.

Fessler *et al.*<sup>117</sup> noted that cathodic protection potentials should not be decreased to compensate for crevices, as potentials that are too low will form hydrogen bubbles in the crevice, which, in turn, will block the protection current. They suggested that the pipe-to-soil potentials should be maintained roughly between  $-0.850$  and  $-1.10$  V ( $\text{Cu}/\text{CuSO}_4$ ) to avoid this problem.

### Glossary

**Adsorption** The surface retention of solid, liquid, or gas molecules, atoms, or ions by a solid or liquid.

**Critical pitting temperature** The lowest temperature at which the growth of stable pits is possible.

**Crystallographic plane** A distinct plane in a crystal lattice.

**Depassivation** Loss of the state of being passive.

**Electropolished** A smooth and polished surface produced by making the specimen the anode in an electrolytic cell.

**Etch** A roughened surface produced by chemical, electrochemical, or mechanical means.

**Hydrolysis** In aqueous solutions of electrolytes, the reactions of cations with water to produce a

weak base or of anions to produce a weak acid.

**Inhibition potential** The potential above which pits repassivate in solutions containing inhibitors.

**Intermetallic compound** A type of phase formed when atoms of two or more metals combine in a fixed ratio to produce a crystal different in structure from the individual metals.

**Protection potential or repassivation potential** Minimum potential below which already existing pits stop growing.

**Vacancy** A site in a crystal unoccupied by an atom.

**Weak acid** An acid that dissociates only partially into hydrogen ions and anions in solution.

## Abbreviations

**CCT** Critical crevice temperature

**CPT** Critical pitting temperature

**ESCA** Electron spectroscopy for chemical analysis

**NMR** Nuclear magnetic resonance

**SCE** Saturated calomel electrode

**SHE** Standard hydrogen electrode

## Symbols

**c.d.** Current density

**$C_i$**  Concentration of component  $i$

**$D_i$**  Diffusion coefficient of component  $i$  ( $\text{cm}^2 \text{s}^{-1}$ )

**$E_c^*$**  Corrosion potential of the metal in the solution inside a pit

**$E_i$**  Inhibition potential

**$E_p$**  Pitting potential

**$E_r$**  Repassivation potential

**$F$**  Faraday constant

**$i$**  Current density ( $\text{A cm}^{-2}$ )

**$j_{\text{pas}}$**  Passive current density

**$j_{\text{pit}}$**  Current density inside a pit

**$J_i$**  Flux of component  $i$

**$K_a$**  Equilibrium constant for the dissociation of an acid

**$*K_1$**  Equilibrium constant for the first step of the hydrolysis reaction

**$K_w$**  Ionic product of water

**$R$**  Gas constant

**$T$**  Temperature ( $^\circ\text{K}$ )

**$x$**  Pit depth (cm)

**$\eta$**  Polarization

**$\phi$**  Electrical potential

## 2.04.1 Introduction

### 2.04.1.1 Definition of the Problem

Numerous metals and alloys, such as aluminum, stainless steel, titanium, zirconium, and so on have a very high practical interest because in many corrosive environments, they remain passive. For example, a 1 mm thick sheet of any of these metals can resist the action of the corrosive environment for several thousands of years. Nevertheless, under certain environmental conditions, the passive surface of these metals can show very localized corrosion points, where the 1 mm sheet can develop a hole in less than 1 h. This process of localized metal degradation is known as pitting corrosion ([Figure 1](#)).

When the possibility of pitting corrosion is suspected, there are several ways by which the problem can be treated. At the design stage of equipment, one possible approach is the selection of alloys that will resist pitting corrosion in the given working environment. If, because of the properties required from the alloy, or because of economical reasons, this solution is not convenient, the other possibility for dealing with the pitting corrosion problem is control of the corrosive

**Figure 1** Pitting corrosion. Numerous metals and alloys, such as aluminum, stainless steel, titanium, zirconium, and so on have a very high practical interest because in many corrosive environments they remain passive, with corrosion current densities of the order of  $j_{\text{pas}} = 10^{-6} \text{ A cm}^{-2}$ . Nevertheless, under certain environmental conditions, the passive surface of those metals could show very localized corrosion points, where the corrosion rate reaches values close to  $j_{\text{pit}} = 1 \text{ A cm}^{-2}$ . This process of localized metal degradation is known as pitting corrosion.

environment. This could be done by controlling the concentration of the pitting-inducing anions, by the use of appropriate inhibitors, by controlling the oxygen content of the corrosive environment, and so on. Most of these subjects will be dealt with in this chapter.

### 2.04.1.2 Anions Producing Pitting in Metals

As shown in [Table 1](#), there is a wide number of anions capable of producing pitting of a variety of metals, in aqueous solutions.<sup>1–37</sup>

It is common to find publications in which some specific properties are attributed to chloride anions that would make them particularly aggressive as

**Table 1** Anions producing pitting in metals

<i>Metal</i>	<i>Aggressive anion</i>	<i>Ref</i>
Aluminum	Cl <sup>−</sup>	1, 2, 3
	Br <sup>−</sup>	1, 2
	I <sup>−</sup>	1, 2
	ClO <sub>4</sub> <sup>−</sup>	1, 4
	NO <sub>3</sub> <sup>−</sup>	1, 5
Cadmium	SCN <sup>−</sup>	6, 7
	Cl <sup>−</sup>	8, 9
	Br <sup>−</sup>	8
	ClO <sub>4</sub> <sup>−</sup>	8
	SO <sub>4</sub> <sup>2−</sup>	8, 9
Iron	Cl <sup>−</sup>	10, 11, 12
	Br <sup>−</sup>	10, 11
	I <sup>−</sup>	10, 13
	ClO <sub>4</sub> <sup>−</sup>	10, 11, 14, 15
	SO <sub>4</sub> <sup>2−</sup>	11, 16, 17
Nickel	Cl <sup>−</sup>	13, 18
	Br <sup>−</sup>	13, 19
	I <sup>−</sup>	13
Stainless steel	Cl <sup>−</sup>	20, 21, 22, 23, 24
	Br <sup>−</sup>	20, 21, 22, 23, 24
	SCN <sup>−</sup>	25
Tin	Cl <sup>−</sup>	26
	ClO <sub>4</sub> <sup>−</sup>	27
	SO <sub>4</sub> <sup>2−</sup>	26
	NO <sub>3</sub> <sup>−</sup>	26
Titanium	Cl <sup>−</sup>	28, 29, 30, 31
	Br <sup>−</sup>	28, 29, 31
	I <sup>−</sup>	29, 32, 33
Zinc	Cl <sup>−</sup>	8, 34
	Br <sup>−</sup>	8, 35
	I <sup>−</sup>	34, 35
	NO <sub>3</sub> <sup>−</sup>	34, 35
	SO <sub>4</sub> <sup>2−</sup>	8, 34, 35
	ClO <sub>4</sub> <sup>−</sup>	35
Zirconium	Cl <sup>−</sup>	29, 32, 33, 36
	Br <sup>−</sup>	29, 32, 33
	I <sup>−</sup>	29, 32, 33
	ClO <sub>4</sub> <sup>−</sup>	37

promoters of pitting corrosion. Nevertheless, this suggestion was dismissed by Hoar<sup>14</sup> as early as in 1947, when discussing the iron pitting mechanism. According to Hoar, the action of the chloride anions should not be related to a strong selective adsorption on the metal, as some authors were suggesting, or to a particularly penetrating power of chlorides into the passive film, as suggested by others. Hoar<sup>14</sup> reported that anions such as ClO<sub>4</sub><sup>−</sup> were as aggressive as Cl<sup>−</sup>. He suggested that the effect of Cl<sup>−</sup>, being a nondepositing ion, had a strong influence on the pH in the electrolyte adjacent to the metal anode. According to Hoar, Cl<sup>−</sup> ions replaced OH<sup>−</sup> ions in the solution close to iron, which was the metal under discussion, thus hindering the process of precipitation of Fe(OH)<sub>2</sub>. On the basis of these ideas, Hoar<sup>27</sup> had been able to show even earlier, in 1937, that tin suffered pitting in NaClO<sub>4</sub> solutions. Comparing anions of similar aggressive power, the reason for finding chloride anions in most of the practical cases of pitting is the extensive distribution of NaCl in nature. In fact, very special care has to be taken to have chloride free environments.

### 2.04.1.3 Three Types of Pitting

When reviewing the literature on pitting, it was found that the mixture of different processes, with similar corrosion shapes, was the source of serious confusion because the same mechanism was attributed to all of them.<sup>38</sup> The review showed that, at least three different types of pitting were being discussed, without any clear distinction among them. They can be identified as:

1. electrochemical depassivation,
2. chemical depassivation,
3. etch pitting.

Electrochemical depassivation is the most common of the three, and from a practical point of view, it is also the most relevant. It is found in neutral and alkaline solutions. It develops on otherwise passive metals, and it is characterized as being associated with a pitting potential. It is observed only above this potential, remaining passive below it. In this chapter, when talking about pitting corrosion, we will be referring to this type of attack.

In certain acid solutions, iron, nickel, and other metals show polarization curves of the type shown in [Figure 2](#). Curves similar to those shown in [Figure 2](#) were reported by Piron *et al.*<sup>39</sup> for nickel and for Inconel alloy, by Nobe and Tobias<sup>40</sup> for iron,

**Figure 2** Typical shapes of the polarization curves for iron, nickel, and their alloys, in aqueous solutions of pure 1 M  $\text{H}_2\text{SO}_4$  and in acid with various contents of NaCl. In pure acid the metal shows an active zone, followed by a passive zone, and finally a current increase because of transpassivity or to oxygen evolution. If the polarization curves are measured in solutions containing various amounts of NaCl, it is observed that the current in the passive zone increases and eventually, at a given NaCl content, passivity fails to appear. If the metal, in pure  $\text{H}_2\text{SO}_4$ , is kept at a potential such as *a*, it becomes passive. If, at this point NaCl is injected into the solution, keeping the potential constant, a current increase will be observed, until the stationary polarization curve for the new solution composition is reached. In the transition from the initial passive state to the new corrosion current, pits are formed on the passive surface, which, in the present chapter, are called chemical depassivation. The potential and the current density values in this figure are arbitrary. The values are in the order of magnitude expected for these metals, but were chosen only for illustration purposes.

by Condit<sup>41</sup> for iron–nickel alloys. Engell and Stolica<sup>42</sup> reported that if iron is passivated in chloride-free sulfuric acid, at a potential somewhere between 0.5 and 1.0 V(SCE), and chloride ions are then injected into the solution, pits are formed on the metal. This type of pitting, resulting from a change in the chemical composition, is classified as chemical depassivation. No pitting potential was found in these experiments, and from Figure 2, it can be concluded that it is the transition from one polarization curve to the curve pertaining to the new solution. From a practical point of view, it is a very uncommon case of corrosion. On the other hand, contrary to the earlier opinion of some authors, there is no evidence that would suggest that the same mechanism is acting both in electrochemical depassivation and chemical depassivation.

A third type of pitting is etch pitting. It is crystallographic in nature, and it was developed mainly as a

technique for metallography. It was described in detail by Ives,<sup>43</sup> and falls outside the scope of this chapter.

This chapter deals with electrochemical depassivation, with some references to chemical depassivation.

## 2.04.2 Experimental Aspects of Pitting

### 2.04.2.1 Pitting Morphologies

In general, when corrosion develops spontaneously, without external currents being applied, pits develop in a very localized way in irregular shapes. Usually, it is observed that once a pit nucleates, no other pits are formed in the surrounding areas. The reason is that while the anodic reaction is concentrated in the pit, the surrounding areas are the location for the cathodic reaction, usually oxygen reduction, which produces local changes in pH, inhibiting the formation of new pits close to the active one.

If, on the other hand, pits are formed by the application of an external current, once they are formed the pits can spread laterally to most of the metal surface. The rate of the spreading of corrosion is controlled by the solubility of the passive film in the acid solution produced inside the pit. For example, pits on cadmium,<sup>9</sup> iron,<sup>12</sup> and zinc<sup>34</sup> were found to spread sideways very easily, while pits on aluminum and stainless steels remained localized, because of the resistance of the passive film to dissolution. In the particular case of stainless steels, pits could remain closed, and the magnitude of corrosion is made visible only after a slight abrasion of the surface film.<sup>44</sup> Closed pits have been reported on stainless steels by Rosenfeld and Danilov,<sup>45</sup> while Yahalom *et al.*<sup>46</sup> observed the initial passive film covering the surface of closed pits. An example of covered pits in stainless steel could be found in the paper by Laycock *et al.*<sup>47</sup> Another example of covered pits, in this case for high purity iron pitted in a sodium chloride solution with a borate buffer, could be found in the paper by Alvarez and Galvele.<sup>48</sup>

When working under controlled electrochemical conditions, it is frequent to find that hemispherical electropolished pits are formed, as shown in Figure 3. These pits were produced on pure aluminum, in a  $\text{NaNO}_3$  solution, at constant potential. Similar pits were reported for iron in chloride and in sulfate solutions, for stainless steels in chloride solutions, and so on. The rounded polished morphology of pitting is the result of the random dissolution of the metal atoms, inside the pit, particularly when such a

**Figure 3** Hemispherical pits on aluminum 99.999% in 1.0 M  $\text{NaNO}_3$  solution at  $E = 1.84 V_{\text{SHE}}$ . (Courtesy S. Fernández and R. M. Carranza).

**Figure 4** SEM picture of the interior of a pit of aluminum 99.999% in 1.0 M  $\text{NaNO}_3$  solution at  $E = 1.84 V_{\text{SHE}}$ . The bottom of the pits covered with corrosion products showing a 'dried mud' structure. (Courtesy S. Fernández and R. M. Carranza).

dissolution takes place through a film of corrosion products, as shown in [Figure 4](#). On the other hand, it is also common to observe that pits could grow developing crystallographic planes. An interesting case is that of pitting of aluminum in chloride solutions. In this system, pits grow developing  $\{100\}$  planes, [Figure 5](#). In the particular case of aluminum, this type of attack can lead to the development of deep tunnels, as shown in [Figure 6](#). The production of these tunnels has a practical use, because it is applied to the production of foils for electrolytic condensers.<sup>49</sup> Crystallographic etching, like that shown for aluminum in chloride solutions, was also found for aluminum in bromide, iodide, and perchlorate solutions.<sup>6</sup> Crystallographic planes inside the pits were also reported for iron in

**Figure 5** Pitting of aluminum in chloride solutions. Aluminum 99.999% in 1.0 M  $\text{NaCl}$  solution at  $E = -0.420 V_{\text{SHE}}$ . (Courtesy S. Fernández and R. M. Carranza).

perchlorate solutions,<sup>15</sup> for cadmium in chloride solutions,<sup>9</sup> for zinc in chloride solutions,<sup>34</sup> and so on.

#### 2.04.2.2 Characteristic Electrochemical Parameters for Pitting

When the use of electronic instruments, such as potentiostats, was introduced in corrosion studies, several potential values, characteristic of the pitting process, were found. The most relevant ones were: pitting potential, repassivation potential, and inhibition potential.

### 2.04.2.2.1 Pitting potential

It was found that electrochemical depassivation, or pitting, did not appear at any arbitrary potential value, but only above a certain potential called pitting potential ( $E_p$ ). Below this potential, no pitting was observed, no matter how long the metal was exposed to the action of the environment. Above  $E_p$ , on the other hand, pitting would start almost immediately, as it was the case with aluminum in chloride solutions, or after a short induction time, as in the case of stainless steels. This pitting potential is a function of the composition of the environment, the temperature, the composition of the alloy, and so on. Figure 7 shows a typical example of an anodic polarization curve, where the pitting potential of aluminum in a NaCl solution is shown.

Curves like that shown in Figure 7 could be drawn by applying a constant potential, and waiting for the current to reach a stationary value. Then, the potential is increased, in steps of  $\sim 10$  mV, and the new current value is recorded. When the pitting potential is reached the current starts to increase, and pits start to develop on the metal surface. This technique for measuring  $E_p$  is usually called the potentiostatic technique. In the early studies of pitting, some authors had doubts about the validity of the pitting potential, suggesting that if the waiting time at constant potential was extended long enough, pitting would be found at potentials below  $E_p$ . In order to test this possibility a constant potential technique was applied to measure  $E_p$ . In this case, a different sample was used at each potential, the samples were kept for an extended time, the current was measured and after the measurement the samples

**Figure 7** Pitting potential ( $E_p$ ). Curve based on measurements for aluminum in NaCl solutions. Reprinted from Galvele, J. R.; De Micheli, S. M. de. *Corros. Sci.* **1970**, *10*, 795–807, with permission from Elsevier.<sup>60</sup>

were observed under the microscope. Figure 8 is an example of this technique. The constant potential measurements confirmed the validity of the pitting potential as a transition potential between passivity and localized corrosion.

Horvath and Uhlig,<sup>50</sup> working with stainless steels and related alloys, defined the pitting potential as the lowest potential at which pitting could not be observed after a 10 h or longer period at constant potential. According to these authors, reproducibility was in the order of  $\pm 5$  mV.

Instead of the above-mentioned potentiostatic technique, which tends to be time consuming, another technique frequently used is the potentiokinetic technique, where the electrode potential is changed at a constant scanning rate, while the current is being recorded. One limitation of this technique is that the pitting potential values found can be slightly high, because not enough time is given for the pits to nucleate. Another technique for measuring the pitting potential was introduced by Pessall and Liu.<sup>51</sup> In this technique, the specimen is exposed to the solution, at constant potential, while the metal surface is scratched with a diamond point, or another sharp instrument, to break the passive oxide film. If the potential is lower than the pitting potential, the exposed metal repassivates in a very fast rate. On the other hand, if the potential is above the pitting potential, the repassivation rate is very slow or no repassivation is observed. By measuring the repassivation time, at different potentials, it is possible

**Figure 8** Constant potential technique for measuring  $E_p$ . Curves based on measurements for aluminum in NaCl solutions. Reprinted from Galvele, J. R.; De Micheli, S. M. de. *Corros. Sci.* **1970**, *10*, 795–807, with permission from Elsevier.

to measure  $E_p$  with dispersion lower than 10 mV. Pessal and Liu developed this technique to solve the problem caused by high dispersion in  $E_p$  found for various metals when using potentiokinetic techniques. For the same reason some authors, when measuring pitting potentials, used various techniques in each system, to make sure that the  $E_p$  values found were reliable.<sup>9,34,48</sup>

#### 2.04.2.2.2 Repassivation potential

Another characteristic potential of the pitting process was described by Pourbaix<sup>52</sup> and it is known as the repassivation potential. Pourbaix reported that pits, which will start to grow at the pitting potential, or above, will keep growing even when the potential is lowered below  $E_p$ , Figure 9. The pits will stop growing only when the potential is lower than a certain value called repassivation potential, or protection potential,  $E_r$ . As found by Suzuki and Kitamura,<sup>53</sup> the value of the repassivation potential is related to the occlusion of the pit. As described later, Wilde and Williams<sup>54</sup> found, for a series of steel alloys, that the bigger the difference between  $E_p$  and  $E_r$ , the more susceptible the alloy was to crevice corrosion.

#### 2.04.2.2.3 Inhibition potential

The third characteristic potential was first described by Schwenk,<sup>24</sup> for stainless steels in chloride solutions containing nitrates. It was reported that in these solutions, when increasing the potential above the pitting potential, the current increased. But eventually a potential was reached above which the pits

were repassivated. This potential was called inhibition potential,  $E_i$ , Figure 10, and it has been reported in numerous systems. Kuzub and Novitskii<sup>55</sup> found that  $E_i$ , for stainless steels in chloride plus nitrate solutions was a function of the chromium content of the steel. At higher chromium contents  $E_i$  was lower, and the inhibition of pitting was easier.

Vetter and Strehblow<sup>11</sup> measured the inhibition potential for iron in perchlorate solutions, for iron and nickel in chloride plus nitrate solutions, and for iron in chloride plus perchlorate solutions. Strehblow and Titze<sup>56</sup> also reported inhibition potentials for iron in bromide plus perchlorate solutions, in iodide plus nitrate solutions, and in iodide plus perchlorate solutions and for nickel in bromide plus nitrate solutions.

While the pitting potential,  $E_p$ , has important practical applications, this does not seem to be the case with the pitting inhibition potential. Keitelman and Galvele<sup>57</sup> studied the anodic behavior of high purity iron in a 0.5 M sodium sulfate solution. They measured the pitting potential of iron in pH 9.0 and pH 10.0 solutions. The pitting potential was found to be very close to the corrosion potential measured in a  $\text{Na}_2\text{SO}_4$ , pH 2.7, pit-like solution. On the other hand, the pitting inhibition potential measured in a 0.5 M  $\text{Na}_2\text{SO}_4$ , pH 10.0, solution was very close to the passivation potential found for the metal in the pit-like solution. The practical use of the pitting inhibition potential was limited, because susceptibility to crevice corrosion was observed at potentials above the pitting inhibition potential. Keitelman and Galvele<sup>57</sup> concluded that the pitting inhibition potential could

**Figure 9** Typical polarization curve showing  $E_r$ : repassivation potential;  $E_p$ : pitting potential for a metal, like stainless steel, in a chloride solution.<sup>38</sup> Reprinted from Galvele, J. R. *Corros. Sci.* **2005**, 47, 3053–3067, with permission from Elsevier.

**Figure 10** Typical anodic polarization curve showing the presence of a pitting potential,  $E_p$ , and an inhibition potential,  $E_i$ .<sup>38</sup> Reprinted from Galvele, J. R. *Corros. Sci.* **2005**, 47, 3053–3067, with permission from Elsevier.

not be used to stop pitting corrosion, because in those areas where a high potential drop could be found, like in a crevice, the pitting inhibition potential was not reached and crevice corrosion developed.

It is important to notice that two different forms of crevice corrosion have just been mentioned. The first one is related to the repassivation potential,  $E_r$ , which can be exemplified by the work by Wand and Newman,<sup>58</sup> and the second one, related to the inhibition potential,  $E_i$ , which is exemplified by the work of Al-Zaharani and Pickering.<sup>59</sup> These two types of crevice corrosion were pointed out recently by Galvele.<sup>60</sup>

## 2.04.3 Effect of the Bulk Solution Composition

### 2.04.3.1 Aggressive Solutions

**Table 1** shows the wide variety of ions capable of producing pitting in various metals. What is common to all of them is that none of those ions produce insoluble compounds with the metal under consideration. Another general property is that all the anions involved produce strong acids and they do not interfere with the hydrolysis reaction of the dissolved metal ions with water. The same metal shows different pitting potentials in different environments, and the differences can be substantial, as shown in **Figure 11** for aluminum. The case of titanium is of high practical interest, because Beck<sup>28</sup> reported that

**Figure 11** Pitting potentials reported for aluminum in various solutions. For references purposes, the pitting potential values were superimposed on an Al-H<sub>2</sub>O potential-pH diagram. (a) Equilibrium values for the reaction of hydrogen evolution. (b) Equilibrium values for the reaction of oxygen evolution. From the pits produced near line (a) it is expected the hydrogen will evolve from the pits. On the other hand, from pits produced on aluminum in nitrate solutions the evolution of nitrogen bubbles was detected.

the pitting potential of titanium in chlorides was very high, being  $\sim 10$  V higher than that in other halide solutions. In some cases, the differences in pitting potentials could be small and with specific deviations. For example, for zinc<sup>34</sup> it was reported that the pitting potential was very similar in solutions containing chlorides, iodides, or sulfates, but the pitting potential measured in nitrate solutions was almost 200 mV higher than that in the previously mentioned solutions.

The pitting potential of a metal is also a function of the aggressive anion concentration. It is a general rule that the higher the aggressive anion concentration, the lower the pitting potential. **Figure 12** shows an example of the relation between pitting potential and NaCl concentration for pure aluminum and some of its alloys with copper. In general, relationships of the type

$$E_p = A - B \log C_x$$

are reported,  $A$  and  $B$  being constants,  $E_p$  the pitting potential, and  $C_x$  the concentration in moles of the aggressive anion. A review of the literature<sup>38</sup> shows that the value of  $B$  varies from metal to metal, going from  $\sim 50$  mV up to  $\sim 100$  mV for pure metals. For Fe-Cr alloys, typical values around 200 mV were reported.

### 2.04.3.2 Inhibitors

When the metal is exposed to the action of a mixed electrolyte, different behaviors are observed. If only one of the anions is aggressive and the other anions are inactive from the pitting point of view, the pitting potential will change as if only the aggressive ions

**Figure 12** Effect of NaCl concentration on the pitting potential of aluminum and some of its alloys. Reprinted from Galvele, J. R.; De Micheli, S. M. de. *Corros. Sci.* **1970**, *10*, 795-807, with permission from Elsevier.

were present. If the content of the aggressive anion is reduced, the pitting potential will decrease. But there is a minimum concentration of aggressive anion, below which no pitting can be produced. This minimum value changes from metal to metal. **Table 2** shows the minimum chloride concentrations found for pitting of various alloys in mixtures of sulfuric acid plus sodium chloride solutions. In this case, only chemical depassivation was considered.

As for electrochemical depassivation, it was observed that a nonaggressive anion could increase the pitting potential value. Leckie and Uhlig<sup>62</sup> as well as Rosenfeld and Danilov<sup>45</sup> studied these effects on austenitic stainless steels. Leckie and Uhlig<sup>62</sup> reported that for chloride ion concentrations higher than 0.1 M, the pitting inhibition efficiency of the studied anions was in the following decreasing order:

Schwenk<sup>24</sup> reported that while  $\text{NO}_3^-$  ion inhibited pitting of stainless steels in chloride-containing solutions, it did not inhibit pitting in bromide containing solutions.

Böhni and Uhlig<sup>63</sup> reported for aluminum similar results to those found for stainless steels in chloride solutions. In the case of aluminum, it was assumed that the metal was immune to pitting when the pitting potential was above  $0.8 V_{\text{SHE}}$ . Böhni and Uhlig<sup>63</sup> found that the inhibition efficiency for aluminum in chloride containing solutions was in the following decreasing order:

De Micheli and Galvele<sup>6</sup> studied the effect of mixtures of anions on the pitting potential of aluminum. They found that in mixtures of chloride plus perchlorate anions, a smooth transition was observed on the pitting potential values. In mixtures of chloride plus

nitrate solutions, a clear inhibition effect of the nitrate ion was observed. Nevertheless, one point of interest is that aluminum, in a 1 M NaCl solution, showed a pitting potential of  $-0.64 V_{\text{SHE}}$ , and the pitting was inhibited by  $\text{NO}_3^-$  ions, but on the other hand, if the potential was above  $+1.84 V_{\text{SHE}}$ , the  $\text{NO}_3^-$  ion itself produced pitting on aluminum.<sup>1,5</sup> In mixtures of sulfate plus chloride anions, the sulfate ion had little effect on the pitting potential of aluminum.<sup>6</sup> The pitting potential values were the same as those found in chloride solutions without sulfate ions. It was only at very low chloride concentrations, less than  $10^{-3}$  M, that sulfate showed some effect on the pitting potential.

The inhibiting effect of sulfate ions in chloride-containing solutions was reported for the pitting of nickel,<sup>64</sup> zirconium,<sup>32</sup> and titanium.<sup>31</sup>

Numerous authors reported that weak acid salts acted as pitting inhibitors for stainless steel and for aluminum in chloride containing solutions. Similar observations were made for other metals. For example, the pitting potential of zinc, in sodium chloride solutions and in sodium perchlorate solutions, was increased by adding borate ions to the solutions.<sup>35</sup> The pitting potential of iron in sodium chloride solutions was also increased by adding borate salts.<sup>48</sup> In numerous applications chromates were found to be very efficient as pitting inhibitors, but the carcinogenic nature of chromate requires the search for alternative solutions.

### 2.04.3.3 pH

According to Kaesche,<sup>65</sup> for aluminum in NaCl aqueous solutions, the pH of the solution had no effect on  $E_p$ , for pH values ranging from pH 2 up to pH 11. For stainless steels, on the other hand, Leckie and Uhlig<sup>62</sup> found that the pitting potential was pH independent up to pH 8, but increased sharply with the pH for higher pH values. Similarly, Alvarez and Galvele<sup>48</sup> found that an increase in pH produced an increase in the pitting potential for iron in NaCl solutions, **Figure 13**. Inhibiting effects due to alkaline solutions were also reported for nickel,<sup>66</sup> cadmium,<sup>9</sup> zinc,<sup>35</sup> and so on.

## 2.04.4 Composition of the Solution inside Pits

### 2.04.4.1 Electrolyte inside Pits

From the earliest studies on pitting it was assumed that the composition of the solution inside the pits

**Table 2** Minimum chloride concentration necessary for chemical depassivation of various metals and alloys in mixtures of  $\text{H}_2\text{SO}_4 + \text{NaCl}$  solutions

Metal	Minimum $\text{Cl}^-$ concentration (N)	Reference
Iron	0.0003	61
Fe-5.6Cr	0.017	61
Fe-20Cr	0.1	61
Fe24.5Cr	1.0	61
Fe-18.6Cr-9.9Ni	0.1	61
Nickel	0.001	18

**Figure 13** Pitting potential of high purity iron, in 1.0 M NaCl at various pH values. Reprinted from Alvarez, M. G.; Galvele, J. R. *Corros. Sci.* **1984**, 24, 27–48, with permission from Elsevier.

was different from that outside. A pH decrease in the solution inside aluminum pits was reported by Edeleanu and Evans in 1951.<sup>67</sup> Hagyard and Santhiapillai,<sup>68</sup> prepared very simple artificial pits on an aluminum sample, and reported that, while the pH of the NaCl solution was 6.2, the pH inside the pit was  $\sim 3.5$ . They also found that the chloride concentration inside the pit increased, reaching values about ten times higher than those in the bulk solution. They also found that the concentrated aluminum chloride solution produced inside the pit could flow by gravity outside the pit, activating the metal surface it touched. Wong and Alkire<sup>69</sup> measured the pH of solution inside naturally occurring pits in aluminum, and confirmed that the pH of the solution inside the pits was between 3 and 4. They also found that the solution flowing from the pits, mentioned by Hagyard and Santhiapillai, was not an  $\text{AlCl}_3$  solution, as earlier believed by various authors, but the dominant species was either  $\text{Al(OH)Cl}_2$  or  $\text{Al(OH)}_2\text{Cl}$ . The distinction between the two species was uncertain because their NMR spectra were similar. According to Wong and Alkire,<sup>69</sup> the efficiency of the anodic reaction of metal dissolution inside the aluminum pits was found to be close to 80%, the side reaction being the evolution of hydrogen gas.

Abundant work on actual pits, as well as crevices, has shown beyond any doubt that the solution inside the pits and crevices has a lower pH and a higher ionic concentration than the bulk solution. For copper in sea water, pH 8, the pH found inside the pits was of the order of 5<sup>70</sup> and for iron, the pH measured inside the pits was  $\sim 3.5$ , while the pH of the bulk solution

could have values between 2 and 10.<sup>71,72</sup> For stainless steels exposed to neutral 0.5 M NaCl solutions, the pH inside the pit was found to be lower than 1.0, while the chloride concentration was 6.2 M.<sup>72</sup>

#### 2.04.4.2 Gas Evolution from Pits

The evolution of gas bubbles from pits was reported in the early studies on pitting. Kaesche reported the evolution of hydrogen from pits of aluminum, growing in a NaCl solution.<sup>65</sup> Evolution of hydrogen was also found from aluminum pits produced in perchlorate solutions.<sup>4</sup> Hydrogen evolution was also reported from pits in iron<sup>73</sup> and titanium.<sup>28</sup> Wexler and Galvele<sup>5</sup> reported gas evolution from pits in aluminum in sodium nitrate solutions, but in this case the gas evolving was found to be nitrogen. This observation was confirmed by Barger and Benson.<sup>74</sup>

An evaluation made of the gases evolved from the pits in titanium and in aluminum showed that the hydrogen evolving was equivalent to  $\sim 10\%$  of the total anodic current in the pit.

#### 2.04.5 Effect of Alloying Elements

It was observed that the pitting potential of a metal could be strongly modified with the use of alloying elements. This is an aspect of high technological interest and abundant work has been done on this subject. It is interesting to point out that there are cases in which the aims of the technological application could be pointing to completely opposite directions. For example, for stainless steels, the main interest was to find alloying elements that could lead to the highest possible pitting potential, and thus obtain a very resistant alloy. On the other hand, with aluminum, one of the technological interests was to find an alloy with the lowest possible pitting potential in sea water. The reason was that aluminum was a very attractive metal to be used as sacrificial anode, for cathodic protection. The limitation was that the pitting potential of aluminum, in sea water, was  $\sim 1$  V higher than the equilibrium potential for the  $\text{Al}/\text{Al}^{3+}$  reaction. Consequently, much work was oriented to the search of alloying elements that could lower the pitting potential of aluminum.

The extensive work on the effect of alloying elements on increasing the pitting potential of stainless steels has been reviewed by various authors.<sup>75–79</sup> In general, chromium, vanadium, molybdenum,

tungsten, rhenium, nickel, and nitrogen were found to be beneficial alloying elements, as all of them increased the pitting potential of stainless steel. On the other hand, alloying elements such as manganese or sulfur were found to be detrimental. As pointed out by Horvath and Uhlig,<sup>51</sup> care should be taken when making extrapolations. These authors found that while molybdenum was beneficial for stainless steels in chloride-containing solutions, it was detrimental in bromide-containing solutions.

Some elements, to be effective, need the presence of a third element. This is the case of molybdenum, in ferrous alloys. It requires the presence of chromium to inhibit pitting, and the higher the chromium content the more effective molybdenum would be.<sup>80</sup> It was found, with binary Fe–Mo alloys, that the pitting potential of Fe–5Mo was only slightly higher than that of pure iron.<sup>81</sup>

Nitrogen strongly increases the pitting potential of austenitic stainless steels in chloride solutions. Osozawa *et al.*<sup>77</sup> studied stainless steels containing from 0.02% to 0.2% N. They found that during corrosion all the nitrogen was transformed into ammonium ion, preventing the lowering of pH before the sites could grow as ordinary pits.

Another metal about which abundant information on the effect of alloying elements is available is aluminum. For aluminum alloys with ~5% of the alloying metal, it is known that copper increases the pitting potential of aluminum in chloride solutions, while zinc decreases it, and magnesium has almost no effect, Figure 14.<sup>82,83</sup>

**Figure 14** Pitting potential of binary Al–Cu, Al–Mg and Al–Zn alloys in 1 M NaCl solution. Reprinted from Muller, I. L.; Galvele, J. R. *Corros. Sci.* **1977**, *17*, 179–193, with permission from Elsevier.

Reding and Newport<sup>84</sup> studied ~2500 aluminum alloys in sea water. The alloys were made with practically all the metals of the periodic table. The purpose of their work was to develop aluminum anodes for cathodic protection in sea water. To measure the efficiency of the alloys, the authors circulated a constant anodic current density and measured the potential as function of time. As an old technique for measuring pitting potentials, the galvanostatic technique, consisted in applying a constant current to the sample in the corrosive environment and measuring the potential reached by the sample,<sup>85</sup> Reding and Newport's results could be used to have a rough estimate of the effect of those alloying elements on the pitting potential of aluminum in sea water, as shown in Figure 15. It is only a rough estimate, as in the galvanostatic technique, various anodic currents were applied to make sure that the same potential was reached. Nevertheless Figure 15 gives an initial idea of what the effect of those alloying elements will be on the pitting potential of aluminum in chloride solutions.

## 2.04.6 Pitting Nucleation Sites

The nucleation pit sites have frequently been found to be related to microscopic features on the metal surface. In stainless steels, the pits are usually related to the presence of inclusions. Smialowski *et al.*<sup>86</sup>

**Figure 15** Estimated pitting potential values for binary aluminum alloys in sea water. The estimation is on the basis of the assumption that the measurements made by Reding and Newport<sup>84</sup> lead to electrode potentials close to those obtained in galvanostatic techniques used for pitting potential measurements.

reported that pits are initiated at nonmetallic inclusions, mixed manganese sulfide inclusions being the most effective ones. According to these authors, in the absence of the sulfide inclusions, chromium oxide particles can nucleate pitting.

For low alloy steels, the preferential sites for nucleation of pits were found to be manganese sulfide particles.<sup>87</sup> For nickel, it was reported that pits nucleated either on surface scratches, on grain boundaries or on nickel sulfide inclusions.<sup>88,89</sup>

Suter *et al.*<sup>90</sup> studied the initiation of individual pits on MnS inclusions on 304 stainless steel, with and without mechanical stress. Working in 1 M NaCl solution, the authors found that in those areas where there were no inclusions, no pitting was nucleated at potentials below oxygen evolution. Specimens with shallow MnS inclusions showed metastable pitting but not stable pitting. Specimens with deep MnS inclusions showed active pitting.

#### 2.04.7 Effect of Temperature

The pitting potentials of stainless steels<sup>53</sup> and of aluminum<sup>91</sup> were found to decrease with an increase in temperature. The case of stainless steels is complicated by various factors. Horvath and Uhlig<sup>50</sup> studied the pitting potentials of Ni, of Cr–Ni, Cr–Fe alloys, and of various stainless steels. When studying the behavior of 15% Cr, 13% Ni stainless steel in 0.1 N NaCl, they reported that the pitting potential measured at 0 °C was 0.5 V higher than that measured at 25 °C. They also found that on adding Mo, the pitting potential at 25 °C increased, and at 0 °C, the pitting potential decreased. Eventually, with near 2.4% Mo a reversion in the pitting potential values was reached, as schematically shown in Figure 16. The authors reported that for 1.3% Mo the pitting potentials at 0 °C and at 25 °C were the same. Another observation made by these authors was that the results obtained in chloride solutions could not be extrapolated to other halide solutions. In 0.1 N NaBr solution, the pitting potential at 25 °C was higher than that at 0 °C, and also the addition of Mo decreased the pitting potential value at both temperatures.

Another example of complex relation between pitting potential and temperature is described by Beck<sup>28</sup> for the pitting of titanium in chloride, bromide, and iodide solutions. According to Beck, in chloride solutions, the pitting potential at room temperature is close to 10 V, and drops to ~1 V at

**Figure 16** Schematic view of the effect of Mo and temperature on the pitting potential for 15% Cr, 13% Ni stainless steel, in 0.1 N NaCl solution, as described by Horvath and Uhlig. Reproduced from Horvath, J.; Uhlig, H. H. *J. Electrochem. Soc.* **1968**, *115*, 791–795.

200 °C. On the other hand, in bromide solutions, the pitting potential of Ti starts at 1.7 V at 0 °C, drops to 0.9 V at room temperature, and remains constant up to above 100 °C. Finally, in iodide solutions, the pitting potential of Ti starts at ~1.0 V at 0 °C, increases to a couple of V at 50 °C, and from this temperature to at least 100 °C it remains almost constant at 0.45 V.

It is taken into account that in most of the cases, polyvalent cations are involved, which means that a variety of oxy- and hydroxyl-compounds can be produced, each of them with a different thermal stability. Besides, there are anions in solutions such as iodides that decompose by oxidation, while others such as nitrates decompose by reduction, giving a variety of chemical products. Considering also that most of these reactions will have different behaviors at different temperatures, it seems very improbable that a unique explanation could be found for the effect of temperature in all the cases of pitting. Most probably, each case will require a separate study.

Related to temperature and pitting, a parameter called critical pitting temperature (CPT) has been introduced in recent times, as described below, and is extensively used for grading stainless steels.

#### 2.04.8 Mechanism of Stable Pitting Growth

A mechanism that attempts to explain stable pit growth, should also explain:

1. the nature of the pitting potential, and its properties;
2. the nature of the repassivation potential, and its properties;
3. the nature of the inhibition potential; and so on.

Historically, the development of mechanisms for pitting was simultaneous with the mechanistic studies of passivity. Pitting being a process of failure of passivity, it is natural that the mechanisms suggested for pitting were closely related to the authors' ideas on passivity. Consequently, in the older literature, it is found that those authors who sustained that passivity was the result of adsorption of oxygen atoms on the metal surface, favored the idea that pitting was the result of preferential adsorption of the aggressive anions, displacing the oxygen atoms.<sup>20,50,62,63,92</sup> Hoar,<sup>14,27</sup> as early as in 1937, questioned the mechanism based on competitive adsorption, supported by Kabanov and the concept of high penetrating power of  $\text{Cl}^-$  for the oxide films, supported at that time by Britton and Evans.

The idea that aggressive anions led to pitting by penetrating the passive film was supported by various authors. But, Vetter and Strehblow<sup>93</sup> pointed out that a migration of polyatomic aggressive anions such as  $\text{SO}_4^{2-}$ ,  $\text{ClO}_4^-$ , or  $\text{SCN}^-$  through a solid layer was not conceivable. Figure 17 illustrates the point made by these authors.

Hoar<sup>14,27</sup> described a different view for the action of the so-called 'aggressive ions.' The new mechanism introduced by Hoar, allowed him to predict new cases of pitting, stating that the only condition required

from the aggressive anion was that it would neither interfere with the process of anodic dissolution of the metal, nor with the hydrolysis reaction of the metal cations with the water molecules. According to Hoar, the  $\text{Cl}^-$  replaced the  $\text{OH}^-$  ions consumed by the metal ions and allowed the pH at the anode to fall to values where no solid products would be formed on the metal surface, but in the bulk of the solution.

Hoar's model of pitting became known as the localized acidification model and received reasonable wide acceptance, because it gave a good explanation of the nature of the aggressive anions, the change in composition inside the pits, and so on. Following Hoar's description, it was perhaps more appropriate to call it the  $\text{OH}^-$  depletion model, but it is just a semantic problem.

The introduction of potentiostats in corrosion studies and the discovery of pitting potentials were causes of concern for the supporters of this model, because it did not predict the existence of a pitting potential. Van Muylder *et al.*<sup>70</sup> were the first to attempt an explanation for the existence of a pitting potential value with an acidification process. They used the E-pH equilibrium diagram for  $\text{Cu-H}_2\text{O}$  to explain pitting of copper in chloride solutions. Figure 18 could be used to explain their ideas. Let us assume that  $\text{pH}_{\text{SOL}}$  is the pH of the bulk solution. Above the potential  $E_1$  the anodic reaction of the metal begins as

leading to localized acidification.

**Figure 17** Relative sizes of metal and ions, for Ni covered with a single layer of  $\text{NiO}$ . Sizes and bond angles from: Linus Pauling, *The Nature of the Chemical Bond*, Cornell University Press, New York, 1960.

**Figure 18** Explanation of the nature of  $E_p$ , on the basis of the ideas of Van Muylder *et al.*<sup>70</sup> Pits became stable only at potentials above  $E_2$ .

Nevertheless, if the electrode potential is lower than  $E_2$ , the acidification will shift locally the system to the immunity region, see **Figure 18**, and the anodic reaction of metal dissolution will stop. Then, any localized acidification will disperse by diffusion of the protons to the bulk solution. According to Van Muylder *et al.*,<sup>70</sup> it is only when the metal reaches the potential  $E_2$  that the solution at the anodic region could reach the value  $\text{pH}_{\text{PTB}}$  **Figure 18**, and the reaction of anodic dissolution becomes thermodynamically possible:

Soluble products will be produced at the anode, and they will not interfere with the corrosion process. This reaction will be followed by the hydrolysis equilibrium:

which will perpetuate the localized acidification in the anodic region.

According to Van Muylder *et al.*<sup>70</sup> mechanism, passivity of the metal by insoluble hydroxides or oxides becomes thermodynamically unstable at potentials above  $E_2$ . In other words, the pitting potential is a thermodynamically based value and is given by eqn [1]. This mechanism was successfully used to explain the pitting potential of copper in chloride solutions. Nevertheless, it failed when applied for example to aluminum, as can be seen in **Figure 11**. It also failed when applied to iron, zinc, and so on. It was found that it did not work with those metals whose  $\text{Me}/\text{Me}^{z+}$  equilibrium potential was lower than that for hydrogen evolution. The model did

**Figure 19** Anodic and cathodic reactions inside a pit.

not take into account the reactions of proton consumption that could take place inside the pit, as shown in **Figure 19**.

This mechanism was modified by Galvele and co-workers to explain the pitting potentials of such metals as zinc, cadmium, aluminum, or iron and the pitting potentials found in the presence of reducible anions or inhibitors.<sup>5,9,12,34,82,83,94-98</sup> These authors introduced an electrochemical kinetic explanation for the pitting potential.

The key point of the mechanism is that there is a pH drop on the anode surface and that this pH drop is a necessary condition to sustain pitting. The rate at which the protons are produced will be given by eqns [1] plus [2]:

On the other hand, the consumption of protons can take place by various processes:

by direct reduction:

by reaction with reducible anions:

by reaction with weak acid anions ( $\text{L}^-$ ):

or by diffusion of protons from the anode region to the bulk solution. The rates for eqns [1], [3], and [4] are

potential dependent, while eqn [5] and diffusion are potential independent.

Assuming that the metal is in an alkaline solution, in absence of reducible anions or buffer ions, but in presence of a strong acid salt, which acts only as a supporting electrolyte, the processes inside the pit can be analyzed. Protons will be produced by reactions [1] and [2], and will be consumed by reaction [3]. Reaction [1] is potential dependent, and the higher the potential, the higher the rate of production of protons. On the other hand, with reaction [3], the lower the potential the higher the rate of consumption of protons. If diffusion of protons from the pit to the bulk solution is ignored, there will be a potential at which the rate of production of protons will be equal to the rate of consumption of protons. This is the potential at which reaction [1] and reaction [3] are equal, and it is the corrosion potential of the metal in the acidified solution inside the pit ( $E_c^*$ ). According to Galvele and co-workers, the corrosion potential of the metal in the pit-like solution is the minimum potential at which pitting can be sustained, so the pitting potential will be

$$E_p \geq E_c^*$$

Actually, to compensate for the protons diffusing from the pit to the bulk solution,  $E_p$  should be slightly higher than  $E_c^*$ .

If reducible anions are present, the pitting potential will have to increase to values at which the anion reduction becomes negligible. For example, the pitting potential for pure Al in 1 M NaCl solutions is  $\sim -0.53 V_{\text{SHE}}$ , while in 1 M  $\text{NaNO}_3$  solutions it is  $+1.70 V_{\text{SHE}}$ . Wexler and Galvele<sup>5</sup> reported that during pitting of Al in nitrate solutions bubbles of  $\text{N}_2$  are evolved from the pits. This indicates that the following reaction is taking place:

This reaction produces a heavy consumption of protons, and as shown by the N- $\text{H}_2\text{O}$  Pourbaix E-pH equilibrium diagrams, a high potential has to be reached for this reaction to become negligible. This is the explanation offered for the high pitting potentials found for Al in nitrate solutions.

One serious criticism to any acidification mechanism for pitting was raised by Vetter and Strehblow.<sup>99</sup> They studied the pitting of iron in a mixture of chloride plus sulfate solutions with phthalate buffer (pH = 5), and observed the formation of small corrosion pits with a diameter of  $\sim 1\text{--}50 \mu\text{m}$ . The authors

calculated the composition changes taking place in a  $2 \mu\text{m}$  pit. Their calculations showed that the current density inside the pit was  $\sim 9 \text{ A cm}^{-2}$ , the pH change was  $+0.85$ , the potential change was  $-0.018 \text{ V}$ , and the change in iron concentration was  $+0.9 \text{ mol l}^{-1}$ . These authors concluded that no significant changes of pH, or any ion concentration could be expected in very small pits. Consequently, a second mechanism, other than that of localized acidification, should be assumed.

Reviewing Vetter and Strehblow's results, it is observed that, contrary to what experience has shown about the composition inside the pits, their calculations did not show a decrease in the pH, but an increase of it. As mentioned above, for iron the pH measured inside the pits was  $\sim 3.5$ , while the pH of the bulk solution could have values between 2 and 10.<sup>71,72</sup> The reasons were that the authors chose to ignore the hydrolysis of the metal ions and that they were studying a case of chemical depassivation.

Galvele<sup>95,96</sup> made an analysis of the transport processes taking place inside a pit, taking into account the hydrolysis of the metal ions. This ion transport analysis showed that not only significant acidification was possible in very small pits, but also that a quantitative explanation could be found for the effect of pH, inhibitors, aggressive ion concentration, and so on, on the pitting potential.

The transport analysis was made in the following way. Let us assume, for the sake of simplicity, that we have a pit like the one in Figure 20. At the bottom of this pit an anodic reaction of the type

will take place. No reaction takes place at the walls of the pit. Thus, a unidirectional pit model is obtained, with considerable simplification in the mathematical treatment that will follow. If pit initiation took place, for example, at the bottom of a crack in the surface oxide film, Figure 20 would be an exact description of the process. For a hemispherical pit, Figure 20 would seem to be a gross oversimplification. But, according to Vetter and Strehblow,<sup>93</sup> the mathematical problem of a hemispherical pit could be transformed into an equivalent plane problem by increasing the diffusion path by a factor of the order of 3. As shown below, when calculating the concentration gradients inside pits, only orders of magnitude are considered, so this correction factor can be ignored.

Reaction [6] is assumed to take place in a sodium or potassium salt of an aggressive but noncomplexing

anion. The pH of the bulk solution, which could have any value, is given as a boundary condition. It is also assumed that reaction [6] is followed by a series of hydrolysis equilibrium reactions of the type:

This equilibrium is known to be very quickly reached,<sup>100</sup> so the reactions in eqn [7] will always be in equilibrium. In the first publication<sup>95</sup> only the first step in reactions in eqn [7] was taken into account. In the second publication<sup>96</sup> all the hydrolysis steps from eqn [7] were considered.

To give an idea of the method used in the calculation, one example of the first publication will be described. The same procedure was used in the other cases. In the first publication<sup>95</sup> only the first step of hydrolysis from eqn [7] was considered. This is a simplified description of the processes taking place inside a pit; but it will give the minimum degree of acidification expected inside the pit.

The flow of ions inside the pit is given by the following equation<sup>101</sup>:

$$\mathcal{F}_i = D_i \frac{dC_i}{dx} + D_i \frac{z_i F}{RT} C_i + \frac{d\phi}{dx} \quad [8]$$

where  $\mathcal{F}_i$  is the flow of ions  $i$ ,  $D_i$  the diffusion coefficient of the same ions,  $C_i$  their concentration,  $x$  the pit depth as shown in Figure 20,  $(d\phi/dx)$  the gradient of potential  $\phi$ ,  $z_i$  the valence of ions  $i$ ,  $F$  the Faraday constant,  $R$  the gas constant, and  $T$  the absolute temperature.

As shown by Vetter and Strehblow,<sup>99</sup> small ionic concentration changes should be expected at pit initiation. So the sodium salt, in the bulk solution, will act as a supporting electrolyte for the species formed in reactions [6] and [7]. This means that the transport of all these species will be due to ion diffusion. The contribution of ion migration can be ignored, which again contributes to a simplification in the mathematical treatment. Consequently, reaction [8] is reduced to:

$$\mathcal{F}_i = D_i \frac{dC_i}{dx} \quad [9]$$

As it is assumed that the bulk solution could have any pH value, the first step in reaction [7] has to be rewritten to account for the contribution of the OH-ions in alkaline solutions:

**Figure 20** Unidirectional pit model used for calculation of the corrosion species present inside a pit. Reprinted from Galvele, J. R. *Corros. Sci.* **1981**, 21, 551–579, with permission from Elsevier.

Species S:	1	2	3	4	5
					[10]

From eqn [10] we find that inside the pit there are five species (S1–S5), the concentrations of which should be calculated. The detailed mathematical treatment for a system like this can be found in Vetter's book on Electrochemical Kinetics.<sup>101</sup> The five unknown concentrations are calculated by resolution of the five following equations:

the flow of the species containing Me atoms will be given by

$$D_1 \frac{dC_1}{dx} + D_4 \frac{dC_4}{dx} = \frac{i}{nF} \quad [11]$$

the flow of the species containing O atoms will be given by

$$D_2 \frac{dC_2}{dx} + D_3 \frac{dC_3}{dx} + D_4 \frac{dC_4}{dx} = 0 \quad [12]$$

and the flow of the species containing H atoms will be given by

$$2D_2 \frac{dC_2}{dx} + D_3 \frac{dC_3}{dx} + D_4 \frac{dC_4}{dx} + D_5 \frac{dC_5}{dx} = 0 \quad [13]$$

Finally, the two following equilibrium relations must be considered

$$^*K_1 = \frac{C_4 C_5}{C_1} \quad [14]$$

which is the law of mass action applied to the first step of hydrolysis in eqn [7], and

$$K_w = C_3 C_5 \quad [15]$$

which is the ionic product of water.

The boundary conditions used in the calculations were  $C_1 = C_4 = 0$ , the values for  $C_3$  and  $C_5$  were given by the pH of the bulk solution. As for the ionic diffusion coefficients, since they were very similar in aqueous solutions, they were taken as  $D_1 = D_2 = D_4 = 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ . The only exceptions were  $\text{OH}^-$  ions, for which a value of  $D_3 = 5.3 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  was used, and  $\text{H}^+$  ions for which a value of  $D_5 = 9.3 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  was used. The equilibrium constants for the hydrolysis reactions of eqn [7] were taken from the literature.<sup>102–104</sup>

The concentrations of all the species inside the pit were calculated as a function of the parameter  $x.i$ ,  $x$  being the length of the pit with  $x = 0$  at the opening of the pit and  $i$  the current density of the reaction [6]. Figure 21 shows the results of the calculations for iron, in a pH 10 solution. The concentration of protons, which remains constant at low  $x.i$  values, shows a sharp increase as soon as  $x.i$  reaches a value of  $10^{-6} \text{ A cm}^{-1}$ . The next question is to find out what pH is necessary to start pitting. From the Pourbaix diagrams a pH value is found for the transition between corrosion and passivity. This value is shown as a cross identified as (a). As pits initiate with current densities close to  $1 \text{ A cm}^{-2}$ , if only  $x.i = 10^{-6} \text{ A cm}^{-1}$  is required to reach the necessary acidification, pits as small as  $0.01 \mu\text{m}$  could be initiated by this mechanism.

One criticism that could be made to the calculations in Figure 21 is that the choice of the critical pH is arbitrary. This objection can be disregarded if instead of using the first hydrolysis step, in eqn [7], all the hydrolysis steps are taken into account.<sup>96</sup> Figure 22 shows an example of these calculations. Again the example given is for iron in a pH 10 solution. For the sake of simplicity, only the iron compounds are shown. For low  $x.i$  values the almost exclusive product is solid  $\text{Fe}(\text{OH})_2$ , but above  $x.i \ 10^{-6} \text{ A cm}^{-1}$   $\text{Fe}^{2+}$  becomes the main corrosion product. Another example of the full hydrolysis calculations, in this case for aluminum, can be seen in Figure 23.

These calculations were made for the ionic concentration diagrams of the following systems:  $\text{Zn}/\text{Zn}^{2+}$ ;  $\text{Fe}/\text{Fe}^{2+}$ ;  $\text{Ni}/\text{Ni}^{2+}$ ;  $\text{Al}/\text{Al}^{3+}$ ;  $\text{Cr}/\text{Cr}^{3+}$ ; and  $\text{Co}/\text{Co}^{2+}$ . It has also been shown<sup>95</sup> that these ion concentration diagrams give a quantitative explanation of the influence of solution pH, buffer ions, and inhibitors, on the pitting potential and they also

**Figure 21** Unidirectional pit model for Fe, assuming that only the first hydrolysis step is relevant. The critical  $\text{H}^+$  concentration is shown by the cross (a). **Figure 22** Percentage of metal compounds inside an Fe pit, according to the full hydrolysis pit model. The critical  $x.i$  value, for pits to start developing, is taken at the point when solid species concentration is equal to soluble species concentration. Reprinted from Galvele, J. R. *Corros. Sci.* **2005**, 47, 3053–3067 and Galvele, J. R. *Corros. Sci.* **1981**, 21, 551–579, with permission from Elsevier.

give an explanation of the existence of a pitting repassivation potential.

By changing the external pH value in the boundary conditions of the above mentioned calculations, it is possible to evaluate the effect of pH on the pitting potential. Figure 24 shows the proton concentrations for unidirectional pits of iron, with external pH values going from 9 to 12. It is observed that by increasing the external pH value, the proton

**Figure 23** Percentage of metal compounds inside an Al pit, according to the full hydrolysis pit model. Reprinted from Galvele, J. R. *Corros. Sci.* **2005**, 47, 3053–3067 and Galvele, J. R. *Corros. Sci.* **1981**, 21, 551–579, with permission from Elsevier.

**Figure 24** Effect of the pH of the bulk solution on  $x.i$ . The higher the pH, the more difficult it is to reach the critical  $x.i$  value for pitting. Reproduced from Galvele, J. R. *J. Electrochem. Soc.* **1976**, 123, 464–474, with permission from the Electrochemical Society.

concentration curve is shifted to higher  $x.i$  values. For a given  $x$  value, this means that with higher bulk solution pH values, higher current density values will be required to attain the same acidification. If the current density inside the pit is potential dependent, as it is generally the case, this higher current density requirement will be reflected as higher pitting potential values.

Using the full hydrolysis model the following critical  $x.i$  values were found:<sup>96</sup>

$$\text{pH} = 0; \quad x.i = 5.0 \times 10^{-7} \text{ A cm}^{-1}$$

$$\text{pH} = 11; \quad x.i = 5.0 \times 10^{-6} \text{ A cm}^{-1}$$

$$\text{pH} = 12; \quad x.i = 5.0 \times 10^{-5} \text{ A cm}^{-1}$$

For pH values above 9 it is observed that an increase in one unit in the pH value leads to an increase of one order of magnitude in the  $x.i$  value. If the relation between potential and current density inside the pit follows a logarithmic law, the pitting potential should be expected to follow a law of the type

$$E_p = A + B \cdot \text{pH} \quad [16]$$

where  $B$  is equal to the Tafel slope for the metal in the acid pit-like solution. Such a relation was found for iron in NaCl solutions (Figure 13)<sup>48</sup> and for cadmium in NaCl and in Na<sub>2</sub>SO<sub>4</sub> solutions,<sup>9</sup> both at pH values above 10. In all these cases, the  $B$  value of eqn [16] was very close to the Tafel slope of the metal in the pit-like solution.

In the case of trivalent metals, as it is the case with aluminum, the presence of a further step of hydrolysis slows down the effect of the external pH on the  $x.i$  value. As shown in Figure 23, the transition from passivity to pitting is not as sharp as for divalent metal ions, Figure 22. Consequently, for comparison reasons, the critical  $x.i$  value chosen was the point where the concentrations of solid Al(OH)<sub>3</sub> and soluble Al<sup>3+</sup> were equal, that is, the intersection point of both concentration curves. The results found were<sup>96</sup>:

$$\text{pH} = 5; \quad x.i = 1.4 \times 10^{-6} \text{ A cm}^{-1}$$

$$\text{pH} = 8; \quad x.i = 2.0 \times 10^{-6} \text{ A cm}^{-1}$$

$$\text{pH} = 10; \quad x.i = 3.1 \times 10^{-6} \text{ A cm}^{-1}$$

According to the full hydrolysis calculation,<sup>96</sup> for divalent metal ions an increase of only one unit in the pH of the bulk solution produced an increase as big as one order of magnitude in the  $x.i$  value. On the other hand, for aluminum an increase of five pH units produced just a two-fold increase in the  $x.i$  value. The conclusion is that the critical  $x.i$  value, for aluminum, is practically independent of the external pH. This conclusion is in agreement with the experimental observations made by Kaesche,<sup>65</sup> who found that the pitting potential of aluminum was not affected by the solution pH.

The presence of anions of weak acid salts is also very important for the localized acidification at the bottom of the pit. If weak acid salts are present, the anions of those salts will react with the protons, and hinder the localized acidification process. The equilibrium involved will be

where HL is the weak acid and L is the weak acid anion. The equilibrium constant of this reaction will be

$$K_a = \frac{C_{L^-} \cdot C_{H^+}}{C_{HL}} \quad [18]$$

If reaction [17] is introduced as a boundary condition in the ion concentration diagrams, the effect of weak acid salts on the localized acidification can be evaluated. **Figure 25** shows the effect of  $10^{-2}$  M borax on the concentration of the various species in a unidirectional zinc pit. **Figure 26** shows how the concentration of protons is shifted to higher  $x.i$  values when the concentration of borax is increased. The higher the borax concentration, the higher the  $x.i$  values necessary to reach the same acidification. An increase of one order of magnitude in the borax concentration leads to an increase of about one order of magnitude in the  $x.i$  value. If the relationship between the potential and the current density inside the pit follows a logarithmic law, we conclude that the pitting potential of zinc should be related to the borax concentration by an equation of the type

$$E_p = A + B \log C_b \quad [19]$$

$C_b$  being the concentration of the borax. The value of  $B$  should be equal to the Tafel slope of the metal in the pit-like solution. Logarithmic relationships of this type between the pitting potential and the

**Figure 25** Effect of a buffer on the proton concentration inside a pit of for Zn. The maximum buffer capacity is found when the concentrations of HL and  $L^-$  are equal. When the concentration of  $L^-$  begins to decrease, the concentration of  $H^+$  increases and the pit becomes stable. Reproduced from Galvele, J. R. *J. Electrochem. Soc.* **1976**, 123, 464–474, with permission from the Electrochemical Society.

buffer concentration for zinc have been reported by Augustynski *et al.*<sup>35</sup> Relationship [19] was also found to work in the case of pitting of high-purity iron in NaCl solutions in the presence of sodium borate as inhibitor.<sup>84</sup>

The efficiency of a weak acid salt as a pitting inhibitor will depend on the way in which the equilibrium of eqn [17] is shifted. The more the equilibrium is shifted to the left in eqn [17] the more efficiently the salt acts as a pitting inhibitor. This is equivalent to saying that the lower the  $K_a$  value, in eqn [18], the more efficient the inhibitor will be.<sup>95</sup>

The ion concentration diagrams can also explain the existence of a pitting repassivation potential, lower than the pitting potential, **Figure 9**. **Figure 27** is a simplified picture of **Figure 21**. As soon as the system reaches a critical  $x.i$  value,  $x.i_1$  in **Figure 27**, the pit will start to grow. If the potential remains constant, the current density will also be constant, but  $x$  will increase with time and so will  $x.i$  ( $x.i_2$  in **Figure 27**). If the potential is then lowered, the current density will drop, but the pit will continue to grow while the  $x.i$  value is higher than  $x.i_1$ . This means that pits will grow at potentials lower than the initiation potential. Finally the pit will stop growing either because the value  $x.i$  is lower than the minimum required for the pit growth to occur, or because the electrode potential is lower than the corrosion potential in the solution inside the pit,  $E_c^*$ . This mechanism explains the observation made by Suzuki and Kitamura<sup>53</sup>: the deeper the pit the lower the repassivation potential.

**Figure 26** Effect of buffer concentration on the  $x.i$  for Zn. Reproduced from Galvele, J. R. *J. Electrochem. Soc.* **1976**, 123, 464–474, with permission from the Electrochemical Society.

**Figure 27** Origin of the repassivation potential,  $E_r$ . At  $x.i_1$  a pit starts to grow and the potential is  $E_p$ . At constant potential  $i$  remains constant but  $x$  increases, leading the system to  $x.i_2$ . If the potential is lowered, the growth of the pit will not stop until  $x.i_1$  is reached. As the value of  $x$  has increased, the value of  $i$  must be lower, which means a lower  $E$  value. The new  $E$  value at which pitting stops is known as  $E_r$ .

If the concentration of the aggressive anion salt is changed over a wide range of values, the assumption that this salt is acting as a supporting electrolyte, which leads to the use of eqn [9], is not valid. Eqn [8] is to be used, which indicates the presence of an extra electrical potential inside the pit. Figure 28 is a simplified diagram where the appearance of a migration phenomenon at high  $x.i$  values is shown. For the sake of simplicity, the hydrolysis reactions have been ignored. The electrical potential, due to the migration phenomenon, starts to increase as soon as the concentrations of  $\text{Na}^+$  ions and  $\text{Cl}^-$  ions from the NaCl solution start to diverge. The electrical potential values, for different NaCl concentrations, and  $x.i$  values are shown in Figure 29.

An important conclusion from the transport process studies<sup>94–97</sup> was the nature of the pitting potential. It was concluded that the pitting potential had no relation with thermodynamic equilibrium, as suggested by Van Muylder *et al.*,<sup>70</sup> but it was given by the following equation:

$$E_p = E_c^* + \eta + \phi \quad [20]$$

$E_p$  being the pitting potential,  $E_c^*$  the corrosion potential in the pit-like solution,  $\eta$  the polarization needed to reach the critical  $x.i$  value, and  $\phi$  the electrical potential induced by the migration of the aggressive anions to the bottom of the pit. The validity of eqn [20] was tested in numerous

**Figure 28** Migration effect inside a pit in a 1 M NaCl solution. The contribution of migration begins when the concentrations of  $\text{Na}^+$  and  $\text{Cl}^-$  start to diverge. The migration also affects the movement of  $\text{Me}^{3+}$  ions, observed in the deviation of the concentration line at lower  $x.i$  values. Reproduced from Galvele, J. R. *J. Electrochem. Soc.* **1976**, 123, 464–474, with permission from the Electrochemical Society.

**Figure 29** Effect of the NaCl concentration on the potential  $\phi$  inside the pit because of migration. Reproduced from Galvele, J. R. *J. Electrochem. Soc.* **1976**, 123, 464–474, with permission from the Electrochemical Society.

publications<sup>38,44,82,83,97,98</sup> and some of the results are shown in Table 3. Eqn [20] was also confirmed in an independent work by Newman *et al.*<sup>105</sup> Besides, calculations and measurements made on high purity zinc in NaCl solutions with various concentrations of borate buffer, under conditions where the aggressive solution was not acting as a supporting

electrolyte, and eqn [8] had to be used, also confirmed the validity of eqn [20] for the calculation of the pitting potential.

### 2.04.9 Passive Film Breakdown

In the previous section, the mechanism of propagation of stable pits was discussed. But, a previous step is the passive film breakdown, a problem that was anticipated in Figure 17. The breakdown of the passive film and the very initiation of pits are two of the not clearly understood aspects of the pitting process.<sup>106</sup> One source of confusion was the fact that no distinction was made between the three different types of pitting described at the beginning of this chapter. Thus, very often mechanisms were suggested for all types of pitting only on the basis of experiments either on chemical depassivation or on electrochemical depassivation. Another source of confusion was related to the nature of passivity. As pitting is a process of passivity breakdown, any mechanism of pitting had to be related to some mechanism of passivity. For a long time, there were strong discussions between those who maintained that passivity was due to an adsorbed monolayer of oxygen and those who claimed that passivity was due to the formation of a three-dimensional oxide film on the metal surface. Those supporting the idea of an adsorbed monolayer based their pitting mechanisms on the idea of competitive adsorption between the passivating and the aggressive species on the metal surface.<sup>107,108</sup> Those in favor of a passive three-dimensional oxide film tried to find a way to undermine that film. As it is now known that the oxide films present on passive metals are at least several monolayers thick, in this chapter it will be assumed that the metal is initially covered by a three-dimensional passivating oxide film. Theories of pit initiation have been classified into two main groups: film penetration and film breaking.

#### 2.04.9.1 Ion Penetration Mechanisms

The early literature on passive films assumed that the oxide film was acting as a static barrier that isolated the metal from the solution. In order to initiate pitting under such conditions some reaction had to take place to bring the metal in contact with the aggressive ions of the solution. One possible way to initiate pits was for the aggressive ions to migrate into the passive film, thus contaminating it. Anion

migration would be stimulated by the high electric field in the film. As a result of changes of the properties of the passive film, high currents could start to circulate through the contaminated zones and pitting would start.<sup>109</sup> Nevertheless, Vetter and Strehblow<sup>93</sup> pointed out that the migration of polyatomic aggressive anions such as  $\text{SO}_4^-$ ,  $\text{ClO}_4^-$ , or  $\text{SCN}^-$  through a solid layer was not conceivable.

The contamination of the passive films by aggressive anions has been confirmed in several cases. In others, the results obtained by different techniques are conflicting. Basing his studies on impedance measurements, Pryor<sup>110</sup> suggested that migration of chloride ions took place into anodized aluminum films. McBee and Kruger,<sup>111</sup> by ellipsometric studies on pure iron, and on Fe–Cr and Fe–Cr–Mo alloys, found that the injection of chloride ions in the medium produced changes in the properties of the oxide film, probably by penetration of the film. These changes were reversible and the properties of the oxide film were recovered after removing the chloride ions from the medium. Nevertheless, it could not be confirmed that the observations made by McBee and Kruger were due to migration of chloride ions into the film. Marcus *et al.*<sup>112</sup> found chloride present in passive films on nickel using electron spectroscopy for chemical analysis (ESCA) and *in situ* radiotracer measurements. The establishment of a critical concentration of chloride in the film is a prerequisite for the localized breakdown of the film. On the other hand, other authors<sup>113–115</sup> found no incorporation of aggressive ions into the passive film prior to pitting.

The point-defect model for passive film growth developed by Lin *et al.*<sup>116</sup> has been used to explain pit initiation by assuming that the aggressive anion adsorption at the outer layer of the barrier film results in the formation of cationic vacancies. The excess of vacancies at the metal/film interface will lead to the formation of voids and pitting initiation.

#### 2.04.9.2 Film Breakdown Mechanisms

There are two different film breakdown models. In one of them, pitting is considered to start at flaws always present in the oxide film<sup>117,118</sup> while in the other pit initiation results from a continuous state of breakdown and repair of the passive film.<sup>119,120</sup> In these models the role of the aggressive anions is to prevent repassivation at the local breakdown sites.

There are theoretical reasons to expect the existence of flaws in the passive film. Fromhold<sup>121</sup>

**Table 3** Comparison between experimental pitting potential values, measured in 1 M NaCl solution and theoretical values calculated with Eqn [20]. Potentials in  $V_{SHE}$

Alloy	$E_p$ theoretical	Ref.	$E_p$ experimental	Ref.
Al 99.99%	-0.54	83	-0.53	1
Al-3Cu	-0.43	83	-0.43	82
Al-3 Mg	-0.56	83	-0.53-0.57	83
Al-3Zn	-0.76	83	-0.75	83
Fe-18Cr	0.60	44	0.58-0.62	80
Fe-18Cr-1Mo	0.73	44	0.64-0.70	80
Fe-18Cr-2Mo	0.88	44	0.70-0.82	80
Fe-18Cr-5Mo	1.03	44	1.00-1.04	80

pointed out that the act of forcing an ionic species through a compact passive film to produce additional film growth will seriously affect the compact film itself. He found that the electrochemical potential gradients inside the film give rise to extremely large stress values, high enough to produce the mechanical breakdown of the passive film and to transform the crystalline structure of the film into an amorphous one. On the other hand, Sato<sup>122</sup> found that mechanical stresses resulting from electrostriction and surface tension effects may exceed the breakdown stress of the oxide film. In a later paper, the author predicted<sup>123</sup> that there is a critical potential above which breakthrough pores would be formed in the film. This critical film breakdown potential is lower as the surface tension at the metal-electrolyte interface is smaller, and hence, the anion adsorption is stronger.

#### 2.04.9.3 Passive Film Breakdown and Metastable Pits

If, as suggested by the film breakdown theories, flaws really exist in the passive film, and if for sustained pit growth a critical  $x.i$  value has to be reached, it is reasonable to expect that, below the pitting potential, incipient processes of pit initiation should exist. Indications of passive film breakdown and repassivation events were reported by Galvele *et al.*<sup>124,125</sup> when studying the repassivation rate of various metals and alloys. The current decay, when measuring repassivation rates, could be described by a relation of the type

$$i = A.t^b$$

where,  $i$  is the current density,  $t$  is the time and  $A$  and  $b$  are constants. A value of  $b = -1$  is typical of a high field film formation reaction, and it is usually related to the formation of a compact highly protective

passive film. Galvele *et al.*<sup>124,125</sup> studied the repassivation rate for zirconium in various halide solutions, as well as for brass in pH 12, 1 M NaNO<sub>2</sub> solution. They observed that at potentials well below the pitting potential the value of  $b$  was  $-1$ . Then there was a region of potentials where an initial value of  $b = -0.5$ , typical of a diffusion controlled process, was observed, but after a few seconds the current density decreased and returned to values expected for a repassivation rate of  $b = -1$ . At higher potentials, close to the pitting potential, the value of  $b$  increases above  $b = -0.5$ , reaching eventually positive values, as is typical in pitting processes. The intermediate potential region, in which the initial repassivation rate is not as fast as at lower potentials but after a short time the highly protective oxide film is reformed, was identified by the authors as the region where passivity breakdown takes place. They also concluded that the repassivation rate technique was very convenient for detecting the passivity breakdown. No other references were found in the literature where this line of work was followed.

On the other hand, many investigators have observed that the formation of a stable pit is preceded by electrochemical noise. The noise events took the form of transient fluctuations of potential under galvanostatic control, or of current fluctuations under potentiostatic control. Such transients have been reported for many years in stainless steel,<sup>51,126,127</sup> and Al,<sup>7,118,128</sup> and were originally attributed to passive film breakdown and repassivation events.<sup>51,122,123,129</sup>

Afterwards, it was found that each of these electrochemical noise events originates from the formation, growth, and repassivation of a microscopic pit.<sup>130-134</sup> These short life pits, now referred to as metastable pits, can form at potentials well below the pitting potential (which is associated with onset of stable pit growth) and during the induction time before the initiation of stable pitting at potentials above the pitting potential.

Metastable pit growth is a characteristic feature of the pitting corrosion of stainless steel in chloride solutions,<sup>130-135</sup> although indications of metastable pitting have also been reported for other metals and alloys such as iron-chromium alloys,<sup>136</sup> aluminum,<sup>137</sup> and titanium.<sup>138</sup> Metastable pits grown on stainless steel are covered by a layer that is a remnant of the passive film<sup>130,131</sup>; the rupture of their covers results in dilution of the local pit environment and repassivation of the pits.<sup>45,139</sup>

Metastable pitting transients exhibited by stainless steels in chloride solutions have a characteristic shape

**Figure 30** Current transients typical of pre-pits.

(Figure 30). The current increases above the background passive current as the pit nucleates and begins to grow. After a short growth period, the metastable pit repassivates and the current quickly decreases to the level of the original passive current. At open circuit, metastable pitting events result in potential transients with a typical shape consisting of a rapid potential drop followed by a slow increase.<sup>140</sup>

There appear to be no discernible differences between metastable pit growth and the early growth of a stable pit.<sup>134</sup> Therefore, studies of metastable pits were performed in order to gain knowledge about the critical factors that determine the stable growth of pits. Two main lines of information may be obtained from such investigations: stochastic data such as a relationship between the nucleation frequencies of metastable and stable pits,<sup>133,141,142</sup> and kinetic data deduced from the analysis of individual current transients.<sup>130,131</sup>

Frankel *et al.*<sup>130</sup> showed that during the metastable pit growth the pit current increases approximately with the square of time. Making the assumption that the pits associated with these transients are hemispherical in shape, they concluded that the current density was approximately constant with time during most of the metastable pit growth. The transients showed lifetimes as long as 15 s, but typically less than 5 s, and their magnitude varied from 4  $\mu\text{A}$  to 20  $\mu\text{A}$ . Other authors found a growth-rate distribution of metastable pits at each potential and that the metastable pit current follows a power law relationship  $I \sim t^n$  with  $n$  between 0.5 and 1.5.<sup>133,142–144</sup>

According to Frankel *et al.*,<sup>130</sup> metastable pit growth is controlled by the Ohmic resistance of the porous pit cover. Pits repassivated when their cover ruptured and the Ohmic barrier was lost. On the

other hand, if a salt film is present when the cover breaks, pit stability is maintained.

Pistorius and Burstein<sup>131,145–147</sup> believe that the rate of growth of individual pits is controlled by diffusion of metal cations from the pit interior, the surface of which is covered with a salt film even before the cover is lost. During metastable growth, the pit depth is too small to account for the diffusion barrier but the perforated cover over the pit mouth provides an additional diffusion barrier which enables the concentrated pit solution to be maintained. The transition to stable pit growth occurs when the pit has grown sufficiently for its own depth to act as a diffusion barrier. The critical condition under which this transition occurs is determined by the magnitude of the product of the pit current density,  $i$ , and its depth,  $a$ , called the ‘pit stability product.’ All pits grow initially in the metastable condition, with a pit stability product which increases linearly with time, but below the critical value. Once the critical value of  $ia$  is exceeded, pit growth is stable and the pit propagates in the absence of the cover.

Because of the small anodic currents generated during individual metastable events and to avoid these transients being obscured by the passive current or simultaneous transients, experiments must be performed by exposing a restricted surface area of the specimen tested. Most metastable pitting research has been carried out using embedded wires of less than 1 mm diameter (10–500  $\mu\text{m}$ ).<sup>130,131,134,135,137,145–148</sup> Events of amplitude down to *ca.* 1 pA in amplitude can be detected if the electrode is small enough. Using very low noise systems, some authors<sup>138,149–151</sup> have observed small current transients, which exhibit a shape different from that of typical metastable pits in that the current increased sharply and then decayed relatively slowly to the background. These peaks were attributed to nucleation and subsequent repassivation events.

Williams *et al.* have presented a statistical model relating the probability of forming a large propagating pit to the nucleation, death, and propagation characteristics of metastable pits.<sup>132,139,142</sup> The proposed statistical model states that the probability that a stable pit is formed is equal to the probability of forming a metastable pit times the probability that the metastable pit survives to become a stable pit. Thus, the nucleation frequency for stable pits is expressed in terms of the nucleation frequency for metastable pits and a probability of repassivation.<sup>133,141,142,152</sup> Underlying this approach is the

concept that if metastable pits form then a stable pit is sure-to-happen at some time.

## 2.04.10 Pitting of Aluminum Alloys

### 2.04.10.1 Pitting and Intergranular Corrosion

In spite of having a rather low pitting potential, aluminum and certain aluminum alloys are successfully used in marine environments, the reason being that the passive film on aluminum is not a good electron conductor and the electrochemical reduction of oxygen is hindered. This is not the case if copper is present in the alloy. It has been found that the presence of copper in the alloy facilitates the reduction of oxygen, **Figure 31**. Thus copper becomes a deleterious contaminant in these environments, because through the cathodic reaction of oxygen, the presence of copper causes an increase in the electrode potential, which gets above the pitting potential of the aluminum alloy.

Pitting can also be the cause of other types of localized corrosion in aluminum–copper alloys. For example, it has been shown<sup>1</sup> that the susceptibility to intergranular corrosion of aged Al–4%Cu alloys is related to the difference in pitting potentials between a solute-depleted zone, surrounding the intermetallic precipitates along the grain boundaries, and that of the grain bodies. As shown in **Figure 12**, the pitting potentials of the grains in chloride containing solutions were almost 100 mV higher than those of

the copper-depleted zone at the grain boundaries. **Figure 12** can be divided into three zones. The first one is below the pitting potential of Al–0.2%Cu, which is in equilibrium with the intermetallic  $\text{Al}_2\text{Cu}$ . In this zone, the alloy will remain passive. The second zone in **Figure 12**, is between the pitting potentials of Al–0.2%Cu and Al–4%Cu. In this area of potentials only the copper depleted zone along the grain boundaries will corrode, giving intergranular corrosion. Finally, in the third zone, in the upper part of the figure, all the phases of the alloy will corrode. Intergranular corrosion would not appear in every corrosive medium, but only in those where the aluminum alloys showed pitting, such as  $\text{Br}^-$ ,  $\text{I}^-$ , and  $\text{ClO}_4^-$ , as shown in **Table 4**. The difference in the pitting potentials was a function of the heat treatment of the alloys and for certain heat treatments the difference was so small that the alloys were rendered immune to intergranular corrosion.<sup>82</sup>

## 2.04.11 Pitting of Stainless Steels

### 2.04.11.1 Pitting and Crevice Corrosion

Pitting and crevice corrosion of stainless steels in chloride solutions are frequently found together, the most frequent observation being that stainless steels will fail most frequently by crevice corrosion, rather than by pitting. The prevalence of crevice corrosion, over pitting, has led to the development of a special cell, known as the Avesta cell, where pitting of stainless steels could be measured without the interference of crevice corrosion.<sup>153</sup>

Susceptibility to crevice corrosion was found to be related with  $\eta$  in eqn [20],<sup>38</sup> as shown in **Table 5**. This observation, together with the explanation of the nature of the repassivation potential,  $E_r$ , given in **Figure 27**, helps to explain the empirical relation found by Wilde and Williams between  $E_r$  and the susceptibility to crevice corrosion of stainless steels in sea water.<sup>54</sup>

Wilde and Williams found an empirical relation that related the difference  $E_p - E_r$  and the susceptibility to crevice corrosion in sea water. The anodic reaction inside the pit allows to explain the data in **Table 5**, as well as the empirical relation found by Wilde and Williams. These authors showed that the larger the difference between the pitting potential and the repassivation potential,  $E_p - E_r$ , the more susceptible the alloy was to crevice corrosion. **Figure 32** shows some of their results. It is important to notice that the technique developed by Wilde and Williams

assumes that the depth of the pits is the same in all the samples under comparison and that this condition is achieved when the current density reaches  $0.2 \text{ A cm}^{-2}$ . Nevertheless, this condition will be true only when the number of pits in all the tested samples is similar.

The explanation for Wilde and Williams's correlation could be found in Figure 33. We will assume that the current density, when pitting starts, is of the order of  $1 \text{ A cm}^{-2}$ . We will also assume that curve (a) shows the Tafel curve for iron in a pit-like solution in NaCl and curve (b) is a pseudo-Tafel curve for stainless steel, this last value being on the basis of

**Figure 32** Comparison between the difference  $E_p - E_r$ , measured potentiokinetically in a NaCl solution, and crevice corrosion measured after long exposures in sea water. Reprinted from Wilde, B. E.; Williams, E. *Electrochim. Acta* **1971**, *16*, 1971–1985, with permission from Elsevier.**Figure 33** Susceptibility to crevice corrosion in NaCl solutions based on the relation inside the pit, for iron (a)<sup>48</sup> and for stainless steel (b)<sup>44</sup> the potential scale is arbitrary, and was chosen for illustrative purposes. In this example the following assumptions are made: critical value  $x \cdot i = 10^{-6} \text{ A cm}^{-1}$ , pit size  $x = 10^{-6} \text{ cm}$ , crevice size  $x = 10^{-4} \text{ cm}$ . In case (a) the difference in potential required to start pitting corrosion from that to start crevice corrosion will be of only 50 mV. In case (b) crevice corrosion will start at a potential 800 mV lower than that required to start pitting.

Galvele *et al.*<sup>44</sup> If the critical  $x \cdot i$  value is of the order of  $x \cdot i = 10^{-6} \text{ A cm}^{-1}$ , pitting could start on any flaw of  $10^{-6} \text{ cm}$ . If the pit is allowed to grow up to  $10^{-4} \text{ cm}$ , to reach again the critical  $x \cdot i$  value the current density will have to drop to  $10^{-2} \text{ A cm}^{-2}$ . In the case of curve (a) the difference  $E_p - E_r$  will be of only 50 mV. On the other hand, the difference  $E_p - E_n$  for curve (b) will be

of 800 mV. If, instead of a pit of  $10^{-4}$  cm, we have a crevice of the same size, in case (a) the difference between pitting and crevice corrosion will be of only 50 mV, a value usually obscured by the corrosion potential oscillations in practical cases, and it could be concluded that metal (a) is not susceptible to crevice corrosion. On the other hand, for metal (b), crevice corrosion will start at a potential 800 mV lower than that required for pitting, and this metal will be more susceptible to crevice corrosion than to pitting.

The relation between pitting and crevice corrosion was supported by Wood *et al.*<sup>118</sup> They studied the evolution of crevice corrosion of AISI type 304 austenitic stainless steel under a 13 mm diameter  $\times$  0.3 mm glass microscope cover slide, at constant potential, in an air saturated 5% NaCl solution of pH 8.0. The development of crevice corrosion was followed with an appropriate optical system. They observed that while at 600 mV<sub>SCE</sub>, pits nucleated on the entire metal surface, at 400 mV<sub>SCE</sub>, pits nucleated only under the glass cover and spread laterally to take the shape of crevice corrosion. According to these authors, their study confirmed the close link between pitting and crevice corrosion in the case of stainless steels, and it strongly suggested that crevice corrosion is really no more than 'lateral pitting' occurring within an occluded area.

### 2.04.11.2 Critical Pitting Temperature (CPT)

Pitting corrosion of stainless steel and nickel base alloys is characterized by the existence of a CPT, which is defined as the lowest temperature at which the growth of stable pits is possible. At temperatures lower than CPT no stable pitting can occur and only transpassive corrosion takes place. Brigham and Tozer<sup>78</sup> introduced the concept of the CPT as a criterion for ranking resistance of different austenitic stainless steels to pitting corrosion: the higher the CPT, the more resistant the alloy is to pitting.

CPT can be determined by exposing steel samples to an oxidized chloride solution such as FeCl<sub>3</sub> and increasing the temperature in a sequence of test periods until pitting is observed.<sup>156</sup>

The CPT can also be determined electrochemically, either by varying the potential at different constant temperatures or by varying the temperature at different constant potentials.<sup>156–159</sup> At temperatures lower than CPT, passivity breakdown is observed at extremely high anodic potentials, corresponding to transpassive dissolution. Just above the CPT, pitting

can occur and breakdown potentials far below those required for transpassivity are measured. The potential independent CPT is then determined as the temperature at which a sudden decrease in breakdown potential from the transpassive range to the pitting range is observed (Figure 34). The CPT of many stainless steels falls in the range of 10–90 °C.<sup>78,159</sup>

If the simultaneous occurrence of crevice corrosion is eliminated, as is the case when the Avesta cell<sup>153</sup> is used, the CPT can be defined with an absolute accuracy of 1–2 °C.<sup>158,159</sup> On the other hand, when crevice corrosion occurs, localized corrosion initiates at a temperature lower than the CPT, which is called critical crevice temperature (CCT) and the transition from high to low breakdown potentials happens over a temperature interval in which intermediate values of the breakdown potential are observed.<sup>160</sup>

The CPT value is virtually independent of pH in the range 1–7,<sup>158</sup> and of chloride concentration in the range 0.01–5 M.<sup>47,158</sup> However, the CPT is affected by the sulfate concentration,<sup>161</sup> and changes appreciably with surface roughness.<sup>162</sup>

Metastable pitting could occur at temperatures below the CPT, but stable pitting was only detected at the conventional CPT value.<sup>135,160,163</sup> This suggested that the CPT transition was related to the ability of a metastable pit to become stable. Assuming that an anodic salt film must be maintained in all stable pits, CPT has been interpreted as a competition between salt film and oxide formation within the pit.<sup>47,163</sup> Below CPT, passivation would prevent pits from achieving the current density necessary to maintain a concentrated local chemistry and the salt

Figure 34 Critical pitting temperature.

layer precipitation is impossible. A slight modification of this model proposed that the CPT is the temperature below which the salt precipitation, rather than stabilizing the anodic process, mediates the oxide passivation in a manner similar to that of the passivation of iron in sulfuric acid.<sup>46</sup> A further refinement of this theory suggests that a stable pit must be able to undercut the surface, thus creating a passivated lacy metal cover that retains the pit contents;<sup>144,164,165</sup> thus the critical event that cannot occur below the CPT is a high rate active film-free dissolution at the undercutting site inside the pit.

### Glossary

**Critical potential for dealloying** Potential above which nanoporosity is formed and the rate of dealloying levels out with time rather than decaying to a very low value.

**High-density site percolation threshold** A site percolation threshold with the additional requirement that all sites forming a percolation path have at least  $m$  like-neighbors, where  $m > 2$ . Written as  $p_c(m)$ .

**Parting limit** Atom fraction of less-noble element in a binary solid–solution alloy below which dealloying does not occur, irrespective of how oxidizing is the potential. Usually lies in the range 0.5–0.6; can sometimes be *ca.* 0.2, for example in  $\alpha$ -brass.

**Percolation theory** Mathematical theory, applied to more-or-less disordered geometrical systems, that deals with the statistics of interconnection of sites or bonds with a specified property (e.g., for a binary metallic solid solution the relevant property is atom identity and the relevant version of the theory is lattice-site percolation).

**Site percolation threshold** Fractional occupancy of sites, usually on a lattice, by a particular

type of entity (e.g., atom of one kind in a binary solid solution) at which long-range connectivity of such sites appears. Written as  $p_c(\text{site})$ .

### Abbreviations

**NAB** Nickel–aluminum bronze

**SCC** Stress corrosion cracking

### Symbols

***a*** Atom diameter or spacing (m)

***b<sub>a</sub>*** Anodic Tafel coefficient (V)

***D<sub>s</sub>*** Surface diffusion coefficient ( $\text{m}^2 \text{s}^{-1}$ )

***E<sub>0</sub>*** Equilibrium metal–metal ion electrode potential (nonstandard metal ion activity)

***E<sub>c</sub>*** Critical potential for dealloying (V)

***F*** Faraday's constant ( $\text{C mol}^{-1}$ )

***i*** Anodic current density ( $\text{A m}^{-2}$ )

***i<sub>0</sub>*** Exchange current density ( $\text{A m}^{-2}$ )

***j*** Diffusion flux ( $\text{mol m}^{-2} \text{s}^{-1}$ )

***p*** Atom fraction in a solid solution alloy

***p\**** The parting limit, expressed as an atom fraction

***S*** Excess interfacial energy per volume of a nanoscale pit in an alloy surface ( $\text{J m}^{-3}$ )

$\eta_{th}$  Thermodynamic shift in equilibrium electrode potential due to curvature (V)  
 $\gamma$  Solid–liquid interfacial energy ( $\text{J m}^{-2}$ )  
 $\Omega$  Molar volume ( $\text{m}^3$ )  
 $\xi$  Blob size or percolation backbone dimension in percolation theory (m)

## 2.05.1 Introduction and Background

### 2.05.1.1 Definition of Dealloying

Dealloying is the selective electrolytic dissolution of a less-noble element from a metallic solid solution or intermetallic compound. The product of this dissolution, which usually requires an oxidizing acidic solution, is a nanoporous metal consisting mostly of more noble element(s). **Figure 1** show the morphology usually seen in dealloyed noble-metal alloys: an interconnected ligament/pore structure with nearly zero net curvature. The size scale of the porosity in these pictures is typical for silver–gold alloys dealloyed in perchloric acid; the more common nitric acid immersion usually gives a larger pore size.

### 2.05.1.2 Use of Dealloying to Make Interesting Nanomaterials

Recently, there has been a resurgence of interest in dealloying,<sup>1–3</sup> driven by potential technological applications and the remarkable properties of the nanoporous products such as near-theoretical strength in compression,<sup>4</sup> a size-scale-dependent elastic modulus,<sup>5</sup> and under a particular alloy composition and dealloying procedure, the formation of a material with an unusual combination of exceptionally low modulus and relatively good mechanical integrity.<sup>6</sup> Many potential applications of dealloyed materials are under investigation, particularly, in the areas of catalysis<sup>7–9</sup> and sensing.<sup>10,11</sup> Metal foils that are dealloyed, on one side, show potential-dependent bending in electrolytes due to surface stress effects and are thought to have potential as microactuators.<sup>12</sup> This literature is quite different from that which is concerned with dealloying as a corrosion problem.

### 2.05.1.3 History of Dealloying

Dealloying is an ancient technology, and was used by several civilizations to gild the surfaces of objects that

were made mainly of copper and/or silver.<sup>13</sup> Such treatments generally involved the application of heat as well as chemical attack, and the resulting surface would have had a good luster due to some consolidation or coarsening of the nanoporous material – an important factor, because ordinary dealloying performed at room temperature gives a brittle, brownish product. There appears to have been a spectrum of techniques, ranging from true dealloying (with a liquid, but not necessarily very aqueous, environment present on the metal throughout) to a dry-oxidation/ aqueous oxide-dissolution cycle. A closely related use of dealloying was for a more macroscopic separation or ‘parting’ of metals – this was also done by a kind of pack cementation, where, for silver–gold alloys, silver was converted into silver chloride by salt, acid, oxidant, and heat. Later – at an uncertain date, some time in the early 1500s – nitric acid first came into use. But, before that, reagents that contained nitric acid had been invented. There are several different recipes in the *Codex Atlanticus* (ca. 1508) on the use of saltpeter (potassium nitrate) as the source of the nitrate ions (Leonardo da Vinci may have written these recipes himself, but they are not in his usual mirror writing).<sup>13</sup> Since then, nitric acid has been the preferred reagent for dealloying of gold alloys.<sup>14</sup>

The key discovery about the parting of gold alloys was that the less-noble metal or metals had to be present above a certain percentage; otherwise, there was no dealloying. So, if one has, say, an alloy with 40 at.% silver and 60 at.% gold, one has to melt it with more silver so that the silver content exceeds ~60 at.%. This discovery may be very ancient, and the ‘parting limit’ was the most striking feature of dealloying. We will return to the parting limit (or rather limits, because there is another one near 20%) later on.

### 2.05.1.4 Dealloying of Industrial Alloys

Dealloying is also a major corrosion problem in industrial alloys – not so much in itself, as a mechanism of general deterioration, but for its role in stress corrosion cracking (SCC). Dezincification of brass must have been noticed in Roman times; but, the first scientific records date from the early twentieth century, when this was a severe problem affecting  $\alpha$ -brass seawater condenser tubes.<sup>15–17</sup> Bengough and May first systematized the addition of arsenic (in amazingly small amounts, less than 0.05 wt%) for dezincification resistance.<sup>18</sup> Another remedial method, more rarely applied, was to reduce the zinc content to below

**Figure 1** Morphology of Ag–Au alloys dealloyed in perchloric acid showing an interconnected ligament/pore structure with nearly zero net curvature. (a) Reproduced from Senior, N. A.; Newman, R. C. *Nanotechnology* **2006**, 17, 2311–2316. (b) Reproduced from Senior's PhD thesis (University of Manchester, ca. 2005).

20%; but, this adversely affected other properties including general corrosion resistance.  $\beta$ -Brass is more susceptible than  $\alpha$ -brass, as one would expect given its higher zinc content. More recently, other copper alloys such as nickel–aluminum bronze (NAB) have shown dealloying,<sup>19</sup> but these are more complex systems as they are usually multiphase. Dealloying has occurred, but rarely, in various other commercial solid-solution alloys that satisfy the basic

compositional requirement. Alloys used as thin films for magnetic or other applications could potentially suffer from atmospheric dealloying.

There are analogous phenomena that occur in gaseous environments, or in vacuum where one element is volatile.<sup>20</sup> For the most part, these appear to involve lattice diffusion, which places them apart from normal electrolytic dealloying, where transport is by surface diffusion, as discussed below.

## 2.05.2 Mechanisms of Dealloying

### 2.05.2.1 Transport of the More Noble Metal

Historically, three types of mechanisms have been proposed to explain how two alloying constituents, intermixed on an atomic scale, can be separated so effectively by electrolytic action. Perhaps the most obvious is that the dissolution is not really selective at all, but that both elements dissolve, then one replates. But, while there is some evidence that this may occur – very locally – during dezincification of brass,<sup>21</sup> it is clearly not operating in the more general case. The second mechanism, promoted by Pickering and Wagner, involves divacancy injection and room-temperature lattice diffusion of these vacancies.<sup>20,22,23</sup> This appears to be inconsistent with the rapid kinetics of dealloying, but as Pickering pointed out, it would account for the common observation of a significant residue of less-noble metal in the dealloyed material, whereas (in his opinion at the time) it would appear impossible that any less-noble metal could survive at such high anodic overpotentials. Later, Pickering rationalized this by postulating a large IR potential drop within the porous structure, so that the overpotential was actually small at the corrosion front.<sup>24</sup> Apart from graded solid solution compositions, he also observed intermediate phase formation in dealloyed  $\epsilon$ -brass by X-ray diffraction.<sup>25</sup> (Remarkably, this exact experiment was first reported in 1933!<sup>26</sup>) This strongly impressed Pickering with the necessity of postulating some bulk diffusion mechanism.

Recently, most authors have preferred to appeal to surface diffusion as the operative transport mechanism for the more noble metal (the intermediate-phase problem has not, to our knowledge, been addressed from this standpoint and would make an interesting study). A.J. Forty and his group made transmission electron microscopy (TEM) observations of the early stages of porosity formation in silver–gold alloys immersed in nitric acid, and developed a model for the parting limit based on surface diffusion and filling of incipient pores.<sup>27–33</sup> They were also very interested in the formation of gold oxide during dealloying, something that affects the mobility of the gold. Sieradzki *et al.*<sup>34</sup> carried out atomistic Monte Carlo simulations of dealloying and reproduced several of the main features including parting limits, which were ascribed (not quite accurately in the case of the ‘55%’ threshold) to site percolation thresholds in the lattice. Erlebacher developed a much more sophisticated simulation scheme, focusing mainly on morphology, kinetics, and potential dependence.<sup>35</sup>

There may be a niche for bulk diffusion as a partial explanation of the volume shrinkage (a few percent to almost 30%) that occurs during dealloying of silver–gold alloys, but some kind of plastic contraction is almost certainly involved.<sup>36</sup>

### 2.05.2.2 Potential Dependence of Dealloying and the Critical Potential

Pickering made comprehensive studies of the electrode potential dependence of dealloying, and the *critical potential* for dealloying ( $E_c$ ). These experiments did not give a meaningful  $E_c$  for  $\alpha$ -brass because copper dissolution intervened<sup>25</sup>; but, in binary gold alloys, he observed the now-famous shape of curve shown in **Figure 2**. Up to a certain potential ( $E_c$ ), the current density is low and almost potential independent; then it increases steeply at  $E_c$ .<sup>29</sup> Uniform nanoporosity forms only above  $E_c$ , although Pickering often referred to ‘pitting’ or localized porosity below  $E_c$ .<sup>37</sup> As more gold is added to the alloy,  $E_c$  increases until, at the parting limit, only the flat, ‘passive’ region is observed. Up to a certain gold content, this behavior was reproduced, with good quantitative agreement with experiment, by Erlebacher’s simulations.<sup>35</sup> Then, a small refinement (prohibition of dissolution of atoms with 10 or 11 neighbors) reproduced the experimentally observed ‘55%’ parting limit almost exactly<sup>38</sup> – **Figure 3**. It was shown that this was close, but not identical, to a high-density percolation threshold for the lattice.<sup>39</sup> The effect of varying the surface diffusion kinetics was surprisingly small – a few percent – **Figure 4**.

Recently, there has been much discussion of the true value and meaning of  $E_c$ . In 1993, Sieradzki gave a model for  $E_c$  based on two effects: thermodynamic (necessity of dissolving less-noble metal from very small clusters of atoms, thus creating a gold surface with very high curvature) and kinetic (necessity of dissolving these atoms at a certain *rate* to avoid infilling by surface diffusion of gold).<sup>40</sup> More recently, it is proposed that an intrinsic critical potential can be identified, in simulation and experiment, that corresponds only to the thermodynamic (curvature) effect.<sup>35,41–43</sup>

A simplified version of Sieradzki’s original model can be written down in a few lines. The random arrangement of atoms in the solid solution can be characterized,<sup>44</sup> in the language of percolation theory, as a ‘blob and string’ arrangement – ‘blobs’ are regions where, statistically, one kind of atom (say, Ag in Ag–Au) is densely clustered, while the ‘strings’ are chains of Ag atoms joining the blobs together.

**Figure 2** Schematic anodic dissolution behavior of a silver-gold or copper-gold alloy undergoing dealloying in a nonoxidizing aqueous acid, showing critical potentials for nanoporosity generation (\*) and the inability to form nanoporosity when the silver or copper content falls below the parting limit.

**Figure 3** Dynamic current-voltage curves generated by the modified MESOSIM code for the indicated Ag contents in Ag-Au (at. %). Dissolution from 10- and 11-coordinated sites is prohibited. Potential ramping rate is  $2 \text{ mV s}^{-1}$ . Reproduced from Artymowicz, D. M.; Newman, R. C.; Erlebacher, J. *Philos. Mag.* **2009**, *89*, 1663–1693.

Another name for the ‘blob’ size is the percolation backbone diameter. We call this quantity  $\xi$ . This can be shown to be approximately given by

$$\xi = \frac{1+p}{1-p} \quad [1]$$

in units of atom diameters ( $a$ ), where  $p$  is the atom fraction of the less-noble element (Ag).

So, the initial surface of the alloy can be considered to be intersected by numerous blobs of Ag that,

when dissolved, create tiny pits with highly curved Au surfaces. These surfaces have a solid-liquid interfacial free energy  $\gamma$ . The excess interfacial energy  $S$  per unit volume of a hemispherical pit created by the dissolution of a typical ‘blob’ (diameter  $\xi a$ , radius  $\xi a/2$ ) is

$$S = \frac{2\gamma}{\xi a/2} = \frac{4\gamma}{\xi a} \quad [2]$$

(neglecting the slight difference in  $\gamma$  that must exist between the gold-rich pit and the original alloy

**Figure 4** Fraction of samples perforated by dealloying as a function of the 'Ag' content with dissolution of 10- and 11-coordinated atoms prohibited and surface diffusivity set to high, intermediate and negligible values, by changing  $v$ . Samples were 100 atomic layers thick and simulations run for a maximum time of  $10^5$  s. Perforation was defined as dissolution of the first atom from the bottom layer. Simulations stopped at perforation or when the elapsed time exceeded  $10^5$  s.  $v$  is the value of the pre-exponential constant  $v_{\text{diffusion}}$  in eqn [1]. Reproduced from Artymowicz, D. M.; Newman, R. C.; Erlebach, J. *Philos. Mag.* **2009**, 89, 1663–1693.

surface.) So, if we multiply  $S$  by the molar volume  $\Omega$ , we obtain the energy per mole. Dividing by Faraday's constant gives us a shift in the equilibrium electrode potential,  $\eta_{\text{th}}$ , for the Ag that was in the pit compared with ordinary bulk Ag:

$$\eta_{\text{th}} = \frac{S\Omega}{F} = \frac{4\gamma\Omega}{F\xi a} \quad [3]$$

This shift is positive, so it represents a thermodynamic contribution to the difference between the ordinary Ag equilibrium potential and the critical potential. So, for  $p > p^*$ , where  $p^*$  is the parting limit ( $\approx 0.55$ ),

$$\eta_{\text{th}} = \frac{4\gamma\Omega(1-p)}{Fa(1+p)} \quad [4]$$

This agrees quite well with observation for Au and Pt alloys, provided that the  $E_{\text{crit}}$  value for the former is measured extremely slowly, to give a so-called intrinsic critical potential. To have easy dealloying, though, it is necessary for the *rate* of dissolution of the Ag blob to exceed the rate at which the pit is infilled by surface diffusion of Au. This requires an additional overpotential  $\eta_k$  that can be written as

$$\eta_k = b_a \log \frac{i}{i_0} \quad [5]$$

with  $i$  being equated to the flux of Au diffusing into the pit at the critical potential (Sieradzki used a linearized kinetic expression rather than this Tafel version). This flux  $j$  is given by a Fickian steady-state diffusion flux of the form

$$j = \frac{\alpha D_s}{\Omega \xi a} \quad [6]$$

where  $\alpha$  is a geometrical coefficient and  $D_s$  the surface diffusivity of Au. So  $\eta_k$  is given by

$$\eta_k = b_a \log \frac{\alpha F D_s (1-p)}{\Omega (1+p) a i_0} \quad [7]$$

and the critical potential  $E_c$  is given by

$$E_c = E_0 + \frac{4\gamma\Omega(1-p)}{Fa(1+p)} + b_a \log \frac{\alpha F D_s (1-p)}{\Omega (1+p) a i_0} \quad [8]$$

### 2.05.2.3 Order and Disorder

Most studies of dealloying have used more or less disordered binary alloys, but comparison of ordered and disordered material have been made for the copper–gold system. The finding is that dealloying is more difficult (requires a higher potential) in the

ordered material.<sup>45</sup> This can be explained by considering the connectivity of less-noble metal atoms in the lattice – the disordered alloy has a cluster structure in which less-noble atoms comprising the dissolution path have many like neighbors, facilitating penetration of the electrolyte.

#### 2.05.2.4 Ternary Element Effects

Ternary element effects in dealloying are both intriguing and practically important. A long time ago, it was suggested that the beneficial effect of arsenic in brass was associated with the blocking of step edges, slowing down the surface diffusion of copper<sup>21,46</sup>; this stops macro-dealloying, but can be detrimental for SCC resistance, as explained below – very fine porosity makes for brittle behavior. Lately, Erlebacher has explored the behavior of Ag–Au–Pt alloys, which show a refined porosity compared with Ag–Au, for possible applications.<sup>47</sup>

#### 2.05.2.5 Why does Brass Dealloy at 20% Zinc?

So why do some alloys show dealloying at the fcc site percolation threshold (20 at.%), while others require 55% of less-noble element? The conditions for dezincification of  $\alpha$ -brass are quite specific – corrosion has to proceed for some time (usually in an aerated chloride solution), then dealloying starts under the resulting porous corrosion product – an extremely old observation. Lucey,<sup>48,49</sup> and later Newman *et al.*,<sup>21</sup> gave different variants of the same explanation – there is an enrichment of copper ions (Lucey referred to solid  $\text{CuCl}$ ) under the corrosion product, then the conditions become very close to *equilibrium* for the copper, and the exchange current density somehow enhances the mobility of copper, exposing more zinc for dissolution (but still respecting the site percolation threshold). Newman *et al.*<sup>21</sup> showed that dezincification could be monitored electrochemically at the equilibrium potential of a copper electrode in solutions containing  $\text{CuCl}_2^-$ , which is the dissolution product of Cu in chloride solutions. An example of one of their dezincified samples is shown in **Figure 5** – in industrial parlance this would be called ‘plug’ or localized type dezincification.

### 2.05.3 Dealloying in Stress Corrosion Cracking

The role of dealloying in SCC is an old subject of discussion. For binary gold alloys, the correlation

**Figure 5** Plug-type dezincification in  $\alpha$ -brass. Reproduced from Newman, R. C.; Shahrabi, T.; Sieradzki, K. *Corros. Sci.* **1988**, 28, 873–886.

between the two is transparent,<sup>50</sup> but the actual mechanism of crack growth (and this may be different for intergranular and transgranular SCC) remains controversial. According to Sieradzki and Newman,<sup>50</sup> both forms of SCC require only a thin dealloyed layer, which triggers a brittle substrate microcrack; such crack jumps in fcc metals are impossible according to traditional mechanics, but evidence for the phenomenon has mounted – it is especially easy to demonstrate for the intergranular variant in silver–gold alloys,<sup>51–54</sup> but also for brass in ammonia.<sup>55</sup> Even those who prefer another microscopic mechanism admit a very high crack velocity, for example,  $20 \text{ mm s}^{-1}$ , in the case of silver–gold, which cannot be rationalized by any continuous-dissolution type of mechanism.<sup>56</sup>

The important industrial alloys where dealloying has been blamed for SCC are austenitic and duplex stainless steels (in hot chloride, chloride– $\text{H}_2\text{S}$ , or caustic solutions) and copper alloys including  $\alpha$ -brass (traditionally in aqueous ammonia but also in simple solutions like copper sulfate). These are more challenging to study, because there is always some simultaneous oxidation of all the alloy components, and the dealloyed layers are thin.<sup>57</sup> A key finding was that the compositional dependences of dealloying and transgranular SCC in brass, exposed to a solution with which copper is equilibrated, are identical.<sup>58</sup> Research on stainless steels using caustic solutions, where nickel is the ‘noble’ metal,<sup>59</sup> has led to another current thread of study in noble-metal alloys – namely the ability to produce a nanoporous dealloyed layer at very low contents of noble metal. If the anodic overpotential is small enough, dealloying can occur in an alloy with only a percent or two of noble metal, and a nanoporous layer can be produced whose composition is not far removed from that of the original alloy.

## 2.05.4 Summary and Future Prospects

At the time of writing (Spring 2009) we are in the midst of a flood of new literature on dealloying. Over the next few years, practical applications of nanoporous metals (catalysts, sensors, actuators, etc.) will flourish. In turn, long-standing practical corrosion phenomena will be illuminated, especially with regard to the micromechanisms of SCC. We can anticipate that practically every case of SCC in solid-solution alloys will be understood better, and improved preventive measures devised, now that such a wide range of new techniques and concepts is being brought to bear upon the properties and applications of nanoporous metals. Corrosion is just like any other subject – it tends to grow at its interfaces with other disciplines. Also, its standing in the wider scientific community grows with the variety of scientists from remote fields who become interested in corrosion phenomena. Just to give one example, attempts by the author to understand the role of minor alloying elements in dealloying and SCC (arsenic in brass; phosphorus in austenitic stainless steel<sup>46</sup>) were quite primitive at the time, but are now of renewed interest with the discovery of ternary Au–Ag–Pt alloys that show very stable nanoporosity.<sup>47</sup> Also, corrosion scientists can contribute to solving new problems that will come with new technologies. When we start to use nanoporous metals in devices, or alloy nanoparticles as electrocatalysts, a range of new corrosion issues will arise, such as the gradual dissolution of residual less-noble metal that may be essential for the desired function (a Pt–Co alloy is under consideration for hydrogen fuel-cell cathode catalyst formulations, and some candidate alloy electrocatalysts are being made by dealloying).

### 2.06.1 Nature of Intergranular Corrosion

Intergranular corrosion (IGC) is a form of localized corrosion that proceeds along grain boundaries, synonymously referred to as intergranular attack (IGA). Localized corrosion at grain boundaries is caused by the anodic dissolution of (i) regions depleted of alloying elements, (ii) second phase precipitates, or (iii) regions with segregated alloying or impurity elements. The remaining part of the exposed surface typically functions as the cathode, and large cathodic areas support the anodic dissolution process. The ratio between cathode and anode is generally in excess of unity, and is dependent on factors such as the volume fraction and distribution of electrochemically active phases, the distribution of deleterious alloying and impurity elements, as well as grain size, particularly in nanocrystalline materials. The corrosion rate is dependent on the prevailing corrosion mechanism, and factors such as the diffusion of species to or from the anodic front can govern the dissolution kinetics.

**Figure 1** Scanning electron micrographs of sensitized austenitic stainless steels with (a) a severely attacked surface after grain dropping, and (b) a dislodged grain on an attacked surface.

IGC occurs in pure metals as well as engineering alloys, and the term sensitization is frequently used to describe microstructure sensitivities to intergranular attack. In stainless steels, for example, sensitization can be caused through the precipitation of chromium-rich carbides at grain boundaries ([Section 2.06.2.2.1](#)). A major characteristic of IGC is the development of a relatively homogenous and uniform depth of attack. The dissolution of grain boundaries causes the dislodgement of grains, often referred to as grain dropping. Grain dropping is responsible for most of the weight loss observed after IGC exposure, and corrosion rates can therefore be several orders of magnitude higher than during general corrosion. The nature of intergranular attack with grain dropping events is shown in [Figure 1](#). A metallographic section with a uniform depth of attack is shown in [Figure 2](#). Nonuniform IGC attack can also occur, and is typically related to microstructure heterogeneities, as well as factors that locally impair the corrosion process. The latter may include, for instance, the coverage of part of an exposed surface with an electrochemically nonactive deposit, or local differences in solution chemistry.

### 2.06.1.1 Theories of Intergranular Corrosion

Three main theories summarize the occurrence of IGC, comprising (i) the element depletion theory, (ii) the microcell or electrochemical theory, and (iii)

**Figure 2** Optical micrographs of two metallographic sections after IGC testing of sensitized austenitic stainless steel. The images highlight the intergranular nature of attack with grain dropping events close to the specimen surface. After IGC testing the sample was etched in 10% oxalic acid to reveal the intergranular nature of attack.

the segregation theory.<sup>1,2</sup> The depletion theory is based on the local impoverishment of an alloy element, such as chromium in the vicinity of chromium-rich carbides. This results in the breakdown of the passive film in the vicinity of these carbides, producing preferred sites for anodic dissolution. The microcell or electrochemical theory is based on the formation of a local electrochemical cell between precipitate and matrix, followed by dissolution of the less noble element or phase. A typical example is the anodic dissolution of second phase precipitates, such as  $\text{Al}_3\text{Mg}_2$  in the 5XXX series aluminum alloys. The segregation theory is based on the presence of an increased concentration of alloying or impurity elements at or in the vicinity of the grain boundary, such as sulfur or phosphorus in stainless steels. Dissolution of these regions is related to the adsorption of these elements at the grain boundary, ultimately changing the chemical and electrochemical activity.<sup>3</sup>

Another theory of IGC also considers local stresses at boundaries, introduced through the nucleation of second phase precipitates.<sup>1,4</sup> Preferred local attack then takes place at these distorted lattices, close to the second phase precipitate. It is also hypothesized that stresses and strains may lead to a higher degree of atomic disorder of the boundary, resulting in a higher driving force for anodic dissolution. Microscopic stresses or strains at grain boundaries possibly play a secondary role in IGC, for example, they may be responsible for enhanced diffusion pathways.

### 2.06.1.2 Metallurgical Aspects

The material composition and associated crystallographic structure have a large effect on the IGC behavior including, (i) the type of alloying and impurity element, (ii) the associated concentrations, (iii) their spatial distributions, and (iv) individual electrochemical activities. The type and concentration of alloying or impurity elements generally determines the crystallographic equilibrium structure of a material, and possible phase transformations change element solubilities and associated diffusivities. For example, increasing the concentration of carbon or the concentration of chromium in austenitic stainless steels, respectively, decreases and increases the time to form chromium depleted zones in the vicinity of chromium-rich carbide precipitates.<sup>4</sup> The spatial distribution and connectivity of susceptible microstructure constituents is also important, since IGC cannot be sustained without an inter-connected network of susceptible entities. Large distances between susceptible constituents

impede or even prevent the formation of a connected intergranular pathway throughout the microstructure. The electro-chemical activity determines the tendency to dissolve individual elements, even if present only in solid solution or bound to complex intermetallic phases. For example, in the 2XXX series aluminum-copper alloys the presence of copper in solid solution raises the electrochemical potential of the matrix phase, and therefore reduces the electrochemical potential difference to copper-rich precipitates.<sup>5</sup>

The IGC behavior is a strong function of cold work and grain size.<sup>1,4,6</sup> Cold work introduces strain energy into the material, producing changes in the microstructure, such as the occurrence of slip bands, microcell arrays, or phase transformations. These changes are strongly dependent on the crystallographic structure and material composition. For instance, in leaner grade austenitic stainless steels (i.e., Type 304), a considerable volume fraction of deformation induced martensite can develop with the introduction of medium to large amounts of cold work (i.e., >20%). The susceptibility to IGC is then governed by the stability and sensitization propensity of the phases present. The application of small amounts of cold work ( $\leq 20\%$ ) prior to sensitization enhances the diffusion of elements along slip lines, and promotes precipitation at grain boundaries. Subsequent sensitization heat treatments have a strong influence on the precipitation kinetics, and the choice of sensitization temperature can change the location for precipitation, from predominantly at grain boundaries to precipitation at slip bands. The application of higher sensitization temperatures can even induce recrystallization. The effect of grain size on the IGC behavior is dependent on the investigated corrosion system,<sup>4</sup> and differing IGC behaviors with grain size have been observed, for example, with exposures to mildly or strongly oxidizing media.<sup>1</sup> In stainless steels, the sensitization propensity has been reported to increase with decreasing grain size, associated with greater amounts of chromium that can enter the grain boundary region and form chromium-rich precipitates in a given time interval.<sup>6</sup> Contrarily, decreasing sensitization propensities with decreasing grain sizes have also been found, attributed to larger grain boundary surface areas and the formation of a less continuous network of precipitates.<sup>1,4</sup>

### 2.06.1.3 Grain Boundary Structure and Networks

Grain boundaries are in a higher state of disorder than the crystal lattice, that is, they represent 2-dimensional

lattice imperfections, with increased surface energies compared to the grain interior. This explains why grain boundaries are more active than the adjacent matrix phase, and can therefore easily be revealed with metallographic etching techniques. A simplified geometric description of a grain boundary crystallographic structure uses five macroscopic degrees of freedom (DOF).<sup>7,8</sup> These include three DOF for the relative misorientation between the crystal lattices of two neighboring grains, and the remaining two DOF for referencing the grain boundary plane to the grain orientations. The relative misorientation is described with a rotation axis (UVW) common to both adjoining grains, accounting for two DOF, and a rotation angle ( $\theta$ ) around this axis, defining the third DOF. Grain orientation relationships (misorientations) can be obtained from 2-dimensional assessments (i.e., a plain metallographic section), but information about the grain boundary plane typically involves 3-dimensional material characterization.<sup>7</sup>

The grain boundary network is heterogeneous, and consists of an assembly of different grain boundary crystallographic structures, with inherently different grain boundary free energies. These energy variations have a large influence on material properties, such as segregation, precipitation, diffusion, and migration behavior. Different grain boundary crystallographic structures therefore have different susceptibilities to IGC, and their resistance can vary as a function of exposure condition. In austenitic stainless steels, for example, the application of an electrolytic nitric acid etch (ASTM E 112),<sup>9</sup> to determine the ASTM grain size, outlines the grain boundary network, without attacking coherent annealing twin boundaries. The coherent twin boundaries have more than one order of magnitude lower surface energy ( $\approx 0.02 \text{ J m}^{-2}$ ) than general high angle grain boundaries ( $\approx 1 \text{ J m}^{-2}$ ), and are therefore more resistant to attack. The application of an electrolytic oxalic acid etch,<sup>10</sup> in contrast, outlines the complete grain boundary network, including coherent twins. This behavior highlights the relationship between exposure condition and grain boundary free energy on material susceptibility.

The connectivity of grain boundaries also plays an important part. Crystallographic constraints, in the form of clustering of crystallographically related boundaries, can create large regions with corrosion resistant or susceptible grain boundary clusters. This is often observed in low- to medium stacking fault energy face centered cubic (FCC) materials, such as copper or austenitic stainless steels. Large regions with clusters of low energy boundaries, such as twins, can

impede the growth of IGC. Further information about grain boundary structure, surface energy and physical property relationships,<sup>11,12</sup> as well as the influence of grain boundary connectivity,<sup>7</sup> can be found elsewhere in the literature.

#### 2.06.1.4 Grain Boundary Susceptibility

Localized attack at grain boundaries is a function of the 3-dimensional grain boundary structure (5 DOF), and reduced susceptibilities to intergranular corrosion are associated with low energy grain boundaries. The group of low energy grain boundaries comprises low angle grain boundaries, as well as certain high angle grain boundary configurations, such as twin boundaries. Low angle grain boundaries, with misorientations below  $15^\circ$ , are typically less susceptible to attack than high angle grain boundaries. The resistance of low angle grain boundaries increases with decreasing misorientation, and threshold angles for grain boundary resistance have also been reported.<sup>13</sup> The presence of a significantly increased fraction of low angle grain boundaries after plastic deformation, however, is responsible for enhanced diffusion pathways and increased IGC propensities.

High angle grain boundaries, with misorientations in excess of  $15^\circ$ , also possess certain low energy configurations which are more resistant to IGC. **Figure 3** shows a grain boundary network of a sensitized austenitic stainless steel with a mixture of attacked and resistant high-angle grain boundaries. Low energy grain boundaries, such as twin boundaries,

**Figure 3** Backscattered scanning electron micrograph of a grain boundary network in a sensitized austenitic stainless steel, with susceptible and immune grain boundaries. (a) Coherent and (b) incoherent twin grain boundaries, as well as some (c) low energy grain boundary segments show full or partial immunity to attack.

generally show a high resistance to IGC. To characterize different grain boundary structures numerous geometric models are available. For microstructure-property investigations, in particular corrosion studies in cubic crystal systems, the coincidence site lattice (CSL) model has frequently been used. This model is based on three macroscopic DOF ( $(\theta)/(UVW)$ ), and does not take the grain boundary plane into consideration. In the CSL model, grain boundaries are defined with the inverse volume density of coinciding lattice atom sites ( $\Sigma$ ), that is, a high density of coinciding atoms is associated with low  $\Sigma$  boundaries. Grain boundaries up to  $\Sigma 29$  are typically considered to be resistant, but large variations in IGC susceptibilities of different grain boundary types have been observed. The misorientation is only an indicator for grain boundary resistance. Increased microstructure resistance is frequently associated with the presence of twin ( $\Sigma 3$ ) grain boundaries, which are usually the most prominent group in the low  $\Sigma$  boundary population.<sup>7</sup>

The most resistant grain boundary is the coherent twin boundary, defined as  $\Sigma 3$  in the CSL model. Coherent twins can be expressed as a symmetrical tilt grain boundary with low-index  $\{111\}$  grain boundary planes. These boundaries therefore have a high density of coinciding atom sites, and a low energy grain boundary plane configuration. Other  $\Sigma 3$  grain boundaries, such as the incoherent twin, are more susceptible to IGC than coherent  $\Sigma 3$  twins. Incoherent twin boundaries are frequently associated with symmetrical tilt boundaries on  $\{112\}$  planes, and have a higher free energy ( $\approx 0.5 \text{ J m}^{-2}$ ) than their coherent counterpart ( $\approx 0.02 \text{ J m}^{-2}$ ). **Figure 3** highlights the difference in twin boundary susceptibility and also gives examples of other resistant low-energy grain boundary segments. Certain low  $\Sigma$  grain boundaries as well as some general high angle grain boundary configurations can also possess low index habit planes, leading to an increased IGC resistance. Additional factors, such as (i) the deviation from exact reference misorientation, (ii) the deviation from low index grain boundary plane configuration (i.e., curved boundary plane), or (iii) grain boundary faceting, can also influence the IGC resistance.

## 2.06.2 Intergranular Corrosion of Metals and Alloys

Aluminum alloys, stainless steels, and nickel alloys are the most common material systems associated

with intergranular corrosion. This section gives a brief review of IGC in common alloy systems, with strategies to mitigate these problems.

### 2.06.2.1 Aluminum Alloys

The occurrence of IGC in aluminum alloys is a function of the material composition, and certain alloying elements are responsible for the prevailing corrosion mechanism. The IGC susceptibility of heat treatable aluminum alloys is mainly related to the quenching and ageing treatment after solution annealing and small changes in these routines can cause significant changes in material resistance.<sup>14</sup> Another important factor for the IGC behavior is also the thermomechanical process history. Alloy groups that have been generally associated with IGC include, precipitation hardenable 2XXX series Al–Cu alloys, work hardenable 5XXX series Al–Mg alloys, and precipitation hardenable 7XXX Al–Zn–Mg alloys. The 6XXX precipitation hardenable Al–Mg–Si series has also shown IGC, but to a far smaller extent than the other alloy groups. The above-mentioned aluminum alloys are also associated with exfoliation corrosion, which is a type of intergranular corrosion which proceeds parallel to the specimen surface. Exfoliation corrosion is related to the development of excessive corrosion products at grain boundaries, indicating a layer-wise spallation of plate-like grain segments. This type of attack occurs in highly orientated microstructures of wrought aluminum alloys. IGC and exfoliation corrosion proceed in a similar manner, but exfoliation has also been found in materials which were not susceptible to IGC.

In 2XXX series Al–Cu alloys, including Al–Cu–Mg and Al–Cu–Li alloys, IGC behavior is primarily influenced by the copper concentration.<sup>5,14,15</sup> Copper in solid solution increases the corrosion potential of the matrix phase, and copper segregation or depletion can cause local variations in the electrochemical potential. Copper-depleted regions are less noble and susceptible to anodic dissolution in particular, if adjacent to copper-rich intermetallic phases such as  $\text{Al}_2\text{Cu}$ ,  $\text{Al}_2\text{CuMg}$ , or  $\text{Al}_2\text{CuLi}$ . Dissolution takes place in narrow regions close to precipitated phases at the grain boundary. Dealloying of copper-containing intermetallic phases, and copper re-precipitation has also been reported to support local dissolution reactions.<sup>5</sup> To reduce IGC susceptibilities, specifically designed heat and quenching treatments can be employed, which produce a uniform distribution of precipitates.<sup>15</sup> In the 5XXX series Al–Mg alloys with more than 3% Mg, the susceptibility to IGC

is typically based on the dissolution of the intergranularly precipitated  $\beta$ - $\text{Al}_3\text{Mg}_2$  phase.<sup>5,15</sup> This phase predominantly precipitates in the temperature range between 50 and 200 °C, due to a rejection of magnesium out of solid solution. Mg-depleted regions have also been found in the vicinity of the  $\beta$ -phase. Electrochemical measurements on bulk  $\beta$ - $\text{Al}_3\text{Mg}_2$  in NaCl solution indicated more electro-negative corrosion and passivity breakdown potentials than the aluminum matrix phase. These potential differences are responsible for the anodic dissolution of the  $\beta$ - $\text{Al}_3\text{Mg}_2$  phase.<sup>5</sup> Microalloying with zinc produces a stable Al-Mg-Zn phase ( $\tau$ -phase) and precludes the precipitation of  $\beta$ - $\text{Al}_3\text{Mg}_2$  in the 5XXX series alloys. In the 7XXX series Al-Zn-Mg alloys, IGC has frequently been attributed to the presence of Mg-rich grain boundary precipitates, as well as intergranular enrichments of Mg and Zn. Copper bearing 7XXX series Al-Zn-Mg-Cu alloys have been reported to contain copper depleted regions at grain boundaries, with an IGC mechanism similar to the 2XXX series Al-Cu alloys.<sup>15</sup> The application of over-aging heat treatments, and the resultant uniform distribution of precipitates can prevent IGC.<sup>15</sup> In the 6XXX series, Al-Mg-Si alloys IGC has been attributed to the anodic dissolution of the hardening phase  $\text{Mg}_2\text{Si}$ .<sup>15</sup>

### 2.06.2.2 Stainless Steels

Stainless steels can broadly be divided into five groups, comprising (i) ferritic, (ii) austenitic, (iii) martensitic, (iv) duplex (austenitic-ferritic), and (v) precipitation

hardenable materials. Different crystallographic structures have different corrosion behavior, often related to variations in diffusivity and solubility. Chromium depletion is the most common cause for IGC in these alloys, and degradation at grain boundaries is normally referred to as sensitization.<sup>1,4,6</sup> Sensitization is brought about by the presence of chromium-rich phases at grain boundaries, such as carbides, nitrides or intermetallic phases.<sup>16</sup> Exposure of sensitized stainless steel to oxidizing media produces intergranular attack at these chromium depleted regions.<sup>1,4</sup> In highly oxidizing media, such as boiling nitric acid, IGC can also occur in annealed stainless steel. This form of attack is generally related to the segregation and preferred dissolution of impurity elements at grain boundaries.<sup>2</sup>

#### 2.06.2.2.1 Sensitization of austenitic stainless steel

Sensitization is caused by thermal or thermomechanical process treatments, such as annealing, welding, or hot working. Exposure of austenitic stainless steels to temperatures between 450 and 850 °C can induce sensitization, due to the precipitation of chromium-rich carbides.<sup>6,16</sup> Figure 4(a) schematically shows sensitized grain boundaries decorated with chromium carbide precipitates and associated chromium depleted zones. Adverse service conditions, in the form of exposure to neutron irradiation in nuclear plant, can also cause sensitization, but without the nucleation of carbides. The amount of depletion typically varies between different boundary types, due to different grain boundary crystallographic structures.

**Figure 4** Schematic illustration of a sensitized grain boundary with chromium carbide precipitates and typical chromium depletion profiles. Longer sensitization treatments increase both the width and depth of the chromium depletion profiles, until chromium replenishment takes place.

The depletion profiles in **Figure 4(b)** show a chromium composition gradient in the direction perpendicular to the boundary, with the shape and depth dependent on applied heat treatment parameters. The depletion is caused by the slow diffusivity of chromium, compared to carbon, producing regions with local chromium impoverishment, followed by a breakdown of the passive film at these regions. In **Figure 4**, the high concentration of chromium at the grain boundary is associated with the presence of chromium-rich carbide precipitates. The influence of reduced chromium concentrations on the anodic behavior of these regions, for example, if exposed to oxidizing environments, is shown in **Figure 5**. Lower chromium concentrations show increased current densities in the active as well as passive regions of the anodic polarization curve.

A major factor for the development of chromium depleted regions is the chromium and carbon content, as well as the solubility of carbon in the matrix phase. Nucleation of carbides is caused by a decreasing solubility of carbon in the austenitic matrix phase with decreasing temperature, for instance on cooling through the sensitization temperature regime.<sup>16</sup> The dominant carbide in austenitic stainless steels is  $\text{Cr}_{23}\text{C}_6$ , but impurity elements, such as nitrogen and boron, as well as alloying elements usually alter this composition. The presence of high nitrogen contents, for example, may cause sensitization through the

nucleation of  $\text{Cr}_2\text{N}$ . The addition of alloying elements, such as molybdenum in higher alloyed stainless steels (i.e., type 316), may also promote the nucleation of intermetallic phases, such as  $\sigma$ -phase  $(\text{FeNi})_x(\text{CrMo})_y$ <sup>16</sup> or  $\chi$ -phase  $(\text{Fe}_{36}\text{Cr}_{12}\text{Mo}_{10})$ .<sup>16</sup>

A typical method to illustrate the sensitization behavior is the time–temperature–precipitation (TTP) diagram, shown in **Figure 6**. TTP diagrams give an indication of the influence of material parameters on the sensitization propensity. **Figure 6(a)** shows the influence of carbon content, and **Figure 6(b)** the influence of grain boundary structure on sensitization. Increasing the carbon content increases the propensity to sensitization at shorter exposure times. The same is observed with different grain boundary structures. Precipitation occurs in the order of decreasing grain boundary energy, starting with a rapid decoration of  $\delta$ -ferrite–austenite interfaces, followed by precipitation at general high-angle, then incoherent twin and finally coherent twin boundaries. Heat treatments in the lower temperature regime, that is, below  $450^\circ\text{C}$ , usually have no significant effect on sensitization due to markedly reduced diffusivities. In the presence of preexisting carbide nuclei, however, sensitization has been reported below  $450^\circ\text{C}$  after prolonged exposure. This is referred to as low-temperature sensitization, and the occurrence may take years before it becomes significant.<sup>6</sup>

**Figure 5** Anodic polarization curves of Fe–9% Ni–x% Cr alloys in deaerated 2 N  $\text{H}_2\text{SO}_4$  solution at  $25^\circ\text{C}$ . Potentials are given versus normal hydrogen electrode (NHE,  $E_h$ ). Reproduced from Osozawa, K.; Engell, H.-J. *Corros. Sci.* **1966**, 6, 389–393.

**Figure 6** Schematic time–temperature–precipitation (TTP) diagram of austenitic stainless steels with the influence of (a) different carbon contents (based on data from Trillo *et al.*<sup>48</sup>), and (b) different grain boundary structures (based on data from Marshall<sup>16</sup> and Bruemmer and Was<sup>49</sup>).

#### 2.06.2.2.2 Prevention of sensitization

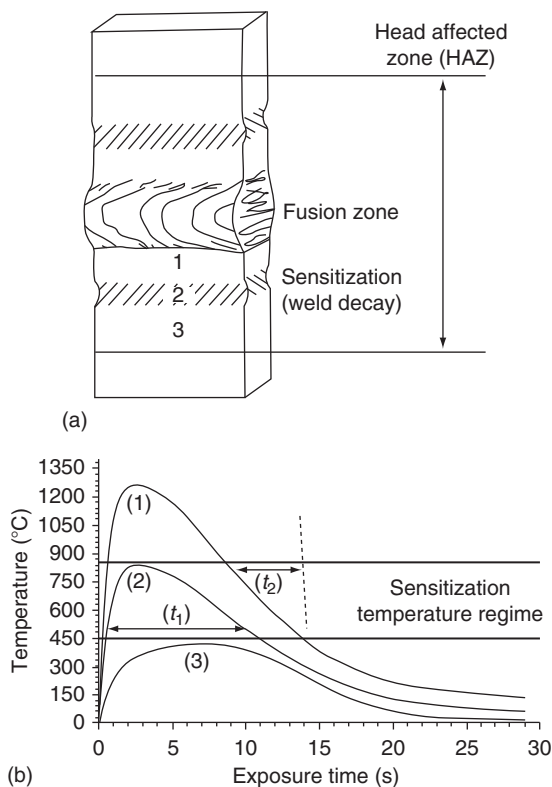

For the prevention of sensitization in austenitic stainless steels, numerous possible mitigation strategies are available. (i) A reduction of the carbon content to concentrations below 0.03% (L-grade) usually prevents sensitization, but prolonged exposures in the sensitization temperature regime may still cause chromium depletion. (ii) The addition of stabilizing elements, such as titanium or niobium (stabilized grades, i.e., Type 321, Type 347), bind carbon into MC-type carbides. This reduces the available carbon in solid solution, and prevents the nucleation of intergranular  $M_{23}C_6$  carbides. Stabilizing heat treatments at temperature in the region of 800–900 °C are

typically applied to precipitate intragranular MC-type carbides. (iii) The application of a solution annealing treatment dissolves existing carbides, and fast cooling/quenching through the sensitization temperature regime prevents carbide nucleation. Typical solution annealing heat treatments for stainless steels are carried out between 1000 and 1150 °C. Sensitization can occur if the material is afterwards heated into the sensitization temperature regime. (iv) Prolonged exposure periods within the sensitization temperature regime can replenish chromium depleted regions with chromium from the grain interior. This is referred to as desensitization treatment. (v) Metallurgical alterations, such as alloying with higher chromium

contents, or the addition of molybdenum, as well as (vi) changes of manufacture or service conditions, such as the reduction of critical exposure temperatures, are possible measures to prevent sensitization.

### 2.06.2.2.3 Weld decay and knife line attack

During welding, in particular fusion-based welding processes, material situated in the fusion zone is locally exposed to temperatures close to the melting point. This induces a temperature gradient with distance from the fusion zone, referred to as the heat affected zone (HAZ), and material within the HAZ can be exposed to temperatures that cause sensitization. On exposure to IGC promoting environments, attack usually takes place in a band parallel to the fusion line. This process is known as weld decay. **Figure 7** shows a typical appearance and location of

**Figure 7** Schematic drawing of the occurrence of weld decay. (a) Weld line with fusion zone, heat affected zone (HAZ) and sensitized region. (b) Typical temperature-time profiles at points 1, 2, and 3 highlight different exposure times within the sensitization temperature regime ( $t_1 > t_2$ ). Reproduced from Procter, R. P. M. Section 1.3 – Effects of Metallurgical/structure on Corrosion. In *Shreir's Corrosion Handbook*, 3rd ed. Metal/Environment Reactions; Shreir, L. L., Jarman, R. A., Burstein, G. T., Eds.; 2000; pp 1–44.

weld decay, and gives three typical temperature profiles (1, 2, 3) with distance from the fusion zone. The time ( $t$ ) at elevated temperature, specimen dimensions, welding process, and associated welding parameters are crucial factors for the occurrence of weld decay.

Knife line attack is associated with IGC in weldments of stabilized stainless steels. This phenomenon occurs after exposing stabilized materials, containing intragranular TiC or NbC precipitates, to temperatures that dissolve these stabilizing MC-type carbides. The required temperature range is typically in excess of 1150 °C, and can occur during fusion-based welding processes. On rapid cooling, neither the MC-type carbides, nor the  $M_{23}C_6$  are precipitated and the carbon remains in solid solution. MC-type carbides are preferentially nucleated at temperatures between 800 and 900 °C, whereas intergranular  $M_{23}C_6$ -type carbides have a stronger driving force for nucleation at lower temperatures. Re-heating to temperatures within the sensitization regime, that is, 450–750 °C, then preferentially precipitates intergranular  $M_{23}C_6$ -type carbides in the HAZ, rendering the microstructure susceptible to IGC. Knife line attack occurs close to the weld bead, since high temperatures are required for the dissolution of the MC-type carbides.

### 2.06.2.2.4 Ferritic, martensitic, duplex, and precipitation hardening stainless steels

Sensitization in ferritic stainless steels is usually caused by the formation of intergranular chromium-rich carbides ( $M_{23}C_6$ ) and nitrides ( $M_2N$ ).<sup>17</sup> Similarly to austenitic stainless steels, chromium depletion is the cause for IGC in mildly oxidizing solutions, and the dissolution of intergranular carbides or segregated elements causes IGC in solutions with a high oxidizing power.<sup>17,18</sup> Rapid precipitation of intergranular carbides has been reported to occur in the sensitization temperature regime between 430 and 930 °C,<sup>17</sup> but annealing in excess of 930 °C, followed by rapid cooling, cannot prevent sensitization. This occurs due to significantly faster diffusivities of chromium, carbon, and nitrogen in ferrite compared to austenite.<sup>17,19</sup> For IGC resistance, desensitization treatments between 700 and 800 °C can be used to replenish the chromium depleted regions.<sup>17</sup> The addition of stabilizing elements, in the form of titanium or niobium, is also common practice to prevent IGC in these materials.

The susceptibility of martensitic stainless steels to IGC is a strong function of the microstructure

condition, and is dependent on the preceding thermal history. Peak hardened microstructures after quenching have an increased resistance to IGC. An increased sensitivity to IGC has been reported after temper annealing at temperatures between 450 and 650 °C, due to the precipitation of intergranular carbides.<sup>1,19,20</sup>

Exposure of martensitic stainless steels to temperatures in excess of 700 °C equilibrates local differences in the chromium content, leading to desensitization.<sup>1</sup>

Austenitic–ferritic (duplex) stainless steels contain ~50% ferrite and ~50% austenite and usually have a good resistance to IGC. These alloys possess higher chromium contents (above 20%), with carbon concentrations far below 0.03%, and modern duplex stainless steels have insufficient carbon for sensitization. Susceptibility of duplex stainless steels is frequently associated with the presence of a critical fraction of austenite–ferrite interfaces.<sup>21,22</sup> In the presence of sufficient carbon, these interfaces are prone to carbide precipitation after short exposure times, due to rapid diffusion of carbon and chromium in ferrite. Narrow chromium depletion regions form at the austenitic side of the interface, due to the slower diffusion kinetics of chromium in austenite.<sup>21,22</sup> Sensitization is not confined to ferrite–austenite interfaces, and chromium depletion also occurs at austenite–austenite boundaries. Desensitization proceeds faster than in austenitic stainless steel, and duplex stainless steels can undergo rapid healing of chromium depleted regions. Generally, intergranular carbide precipitation occurs at temperatures between 450 and 850 °C,<sup>4</sup> with solution annealing usually carried out at temperatures in excess of 1000 °C. Duplex stainless steels also undergo complex precipitation and decomposition reactions, with the formation of intermetallic phases such as  $\sigma$ -phase and  $\chi$ -phase.<sup>16,20</sup> These intermetallic phases are rich in chromium and molybdenum, usually nucleate at grain boundaries, and can cause local element depletions, rendering duplex stainless steels susceptible to IGC.

Precipitation hardenable stainless steels, such as the martensitic 17-4 PH grade (17%Cr/4%Ni/4%Cu) derive their strength from the nucleation of intermetallic strengthening phases on ageing. These strengthening phases are typically soluble in austenite, and precipitate on the formation of martensite. Fully austenitic alloys are also available, which are strengthened by intermetallic precipitates, such as Ni<sub>3</sub>Ti. Sensitization in these materials typically occurs on heat treating and reversion of martensite into austenite, often associated with the HAZ after

welding.<sup>1</sup> Precipitation hardenable stainless steels are susceptible to sensitization similar to their austenitic counterparts, with temperatures up to  $\approx$ 850 °C.

### 2.06.2.3 Nickel and Nickel Alloys

Structural nickel alloys can broadly be grouped according to their main compositional constituents, comprising nickel–chromium–iron alloys (Ni–Cr–Fe), nickel–chromium–molybdenum alloys (Ni–Cr–Mo), and nickel–molybdenum alloys (Ni–Mo).<sup>1,3,4</sup> These alloy systems behave similarly to austenitic stainless steels, and the main alloying elements for improved IGC resistance are chromium and molybdenum. Chromium gives resistance in oxidizing media, whereas molybdenum increases the resistance in reducing media. Nickel has a low solubility of carbon, and even concentrations below 0.03% can cause sensitization due to the precipitation of chromium-rich carbides. Chromium nitrides and the presence of certain intermetallic phases can also cause sensitization, as well as segregated elements, such as sulfur or phosphor. For instance, IGC in pure nickel can occur through the presence of sulfur segregation at grain boundaries, with the extent dependent on the grain boundary crystallographic structure and the exposed environmental condition.<sup>23</sup>

Ni–Cr–Fe<sup>1,3,4</sup> alloys are the largest group of nickel-based alloys. The chromium content typically varies from 15% in the basic grades, for example, alloy 600, to far in excess of 30% in the higher-alloyed materials, such as alloy 690. For increasing the corrosion and pitting resistance, 2–3% molybdenum and copper are frequently added. Molybdenum bearing alloys, however, can develop complex carbides and intermetallic phases. Depending on the carbon content, Ni–Cr–Fe alloys are susceptible to sensitization in the temperature range between 450 and 850 °C, forming carbides of type M<sub>23</sub>C<sub>6</sub> and M<sub>7</sub>C<sub>3</sub>. Solution annealing with fast quenching routines can be used to prevent sensitization.

Ni–Cr–Mo<sup>1,3,4</sup> alloys have a higher resistance to localized corrosion, due to the presence of increased concentrations of molybdenum, typically between 10% and 20%, such as alloy 22. The combination of high chromium and increased molybdenum contents make these alloys highly resistant to a broad spectrum of oxidizing and reducing environments. In contrast, the presence of molybdenum creates more complex carbides and intermetallic phases. Sensitization depends on the carbon content, but can occur between 600 and 1150 °C. The microstructure

nucleates carbides of type  $M_6C$ ,  $M_{23}C_6$ , and  $M_2C$ , producing regions depleted in chromium and molybdenum. Solution annealing only becomes effective at temperatures in excess of 1220 °C.<sup>4</sup> Additional elements such as copper, tantalum, and tungsten are often incorporated to improve the corrosion resistance.

Ni–Mo<sup>3</sup> alloys typically contain 25–30% molybdenum, and can form ordered intermetallic phases of the types  $Ni_4Mo$  and  $Ni_3Mo$ . These alloys have an excellent resistance to reducing media, and IGC occurs in regions depleted of molybdenum. Intergranular carbides, such as  $M_2C$ ,  $M_6C$ ,  $M_{12}C$ , can also form. To prevent sensitization, materials with carbon contents below 0.005% are utilized. Knife-line attack can occur if these alloys are heated in excess of 1250 °C.<sup>3</sup>

#### 2.06.2.4 Other Metals and Alloys

Most metals and alloy systems are susceptible to IGC, and a few examples of different alloy systems are briefly summarized. Copper is susceptible to IGC with exposure to certain etching solutions, such as mixtures of hydrochloric and acetic acid, as well as in solutions containing high concentrations of ammonia.<sup>24</sup> Brass is intergranularly attacked by ferric sulfate and cobalt sulfate,<sup>24</sup> and iron is susceptible to IGC in ammonium nitrate solutions.<sup>25</sup> Pure zinc,<sup>26</sup> containing small amounts of lead, tin, aluminum, or other impurity elements, shows a strong sensitivity to IGC when exposed to hot water or steam environments. Zinc alloys with 4% and 12% aluminum also suffer from IGC in concrete, which is mostly attributed to the segregation of impurity elements and the formation of aluminum rich grain boundary phases.<sup>26</sup> Zirconium shows IGC after immersion in high concentrations of hydrochloric acid containing small amounts of oxidizers, such as ferric- or cupric-ions.<sup>27</sup> More examples of localized attack can be found in the individual material sections of this book.

### 2.06.3 Intergranular Corrosion Testing

Intergranular corrosion testing is carried out either under real service conditions, in simulated service environments, or in accelerated test environments. Accelerated tests are required to rank exposed materials in a similar order as exposure to real service environments. However, the rates of degradation in these tests may not have any relation to the actual

service environment. For accelerated IGC testing, numerous standard practices and test methods are available, but IGC testing can also be carried out in nonstandardized environments. Calculated corrosion rates after IGC exposures are based on the same principles as for general corrosion, implying a homogeneous dissolution. Localized attack must be reported separately.

#### 2.06.3.1 Standard Practices and Test Methods

A range of standard practices and test methods for the assessment and ranking of IGC behaviors are available, and have been published under the auspice of different organizations and institutions. These include the International Standard Organization (ISO),<sup>28–33</sup> the National Association of Corrosion Engineers (NACE) and the American Society for Testing Materials (ASTM).<sup>10,34–41</sup> A large number of national standards are also available. In this section, ASTM and ISO standards for assessing the IGC behavior of aluminum alloys, stainless steels, and nickel alloys are summarized. **Table 1** gives the standard practices for IGC of aluminum alloys, **Table 2** for IGC testing of stainless steels and **Table 3** for nickel alloys. Exfoliation tests for aluminum alloys are also included in **Table 1**.

IGC tests in **Table 1** dissolve specific material constituents that are characteristic of individual aluminum alloys. The tested specimens are either assessed with weight loss measurements, in the case of exposure to nitric acid (ASTM G 67),<sup>38</sup> or using metallographic sectioning methods. Both exfoliation tests in **Table 1** are assessed by visual examination of the exposed surfaces. IGC tests in chloride containing solutions (ISO 11846, ISO 15329)<sup>32,33</sup> produce, with anodic polarization, a localized breakdown of the passive film, which results in either intergranular or intragranular pit initiation sites. The location of these initiation events is then used for material discrimination, with intergranular sites identifying IGC susceptible materials. Further analysis may also comprise an assessment of the extent of intergranular attack, in order to categorize the material with susceptibility ratings. Information about the influence of individual alloying elements, changes in electrolyte concentrations, or the influence of exposure parameters can be found in the literature, including the ASSET<sup>42</sup> (ASTM G 66),<sup>41</sup> EXCO<sup>42</sup> (ASTM G 34),<sup>34</sup> nitric acid<sup>43</sup> (ASTM G67),<sup>38</sup> and chloride/peroxide<sup>14</sup> (ASTM G 110/ISO 11846)<sup>33,36</sup> test.

**Table 1** ASTM and ISO practices for IGC and exfoliation testing of aluminum alloys

<i>Standard</i>	<i>Test solution</i>	<i>Materials</i>	<i>Nature of attack</i>	<i>Duration / temperature</i>
ASTM G 34 (2001)	Sodium chloride, potassium nitrate, nitric acid -EXCO-	Wrought; AA2XXX, AA7XXX	Exfoliation	≤48–96 h/25 °C
ASTM G 66 (1999)	Ammonium chloride, ammonium nitrate, ammonium tartrate, hydrogen peroxide -ASSET-	Wrought, AA5XXX (>2% Mg)	Exfoliation	24 h/65 °C
ASTM G 67 (2004)	Nitric acid -NAMLT-	Wrought, AA5XXX (Al–Mg; Al–Mg–Mn)	GB precipitation (Al <sub>3</sub> Mg <sub>2</sub> )	24 h/30 °C
ASTM G 110 (2003)	Sodium chloride, hydrogen peroxide	Wrought + cast; AA2XXX, AA6XXX, AA7XXX	GB precipitation	>6 h/30 °C
ISO 11846 (2008)	(Method A) sodium chloride, hydrogen peroxide	Wrought + cast; AA2XXX, AA6XXX, AA7XXX	(Method A–C) GB precipitation	>6 h/30 °C
	(Method B) sodium chloride, hydrochloric acid	Wrought + cast; Solution heat-treatable Aluminum alloys		24 h/RT
	(Method C) anodic polarization in sodium chloride	Aluminum–lithium alloys		Polarization/RT
ISO 15329 (2008)	Sodium chloride	Wrought + cast; Solution heat-treatable AA2XXX, AA6XXX, AA7XXX, AA8XXX	GB precipitation	Polarization/RT

RT = Room temperature, GB = Grain boundary.

IGC tests for austenitic, ferritic, and duplex stainless steels are summarized in **Table 2**. Two different test methods are typically distinguished, on the basis of either material quality testing or sensitization propensity testing. The later assessment involves the exposure of materials to short sensitization heat treatments before IGC testing, with the aim to provide information about the propensity of the material to develop a sensitized grain boundary network. Material quality testing is typically carried out without any additional heat treatment. The IGC tests in **Table 2** are assessed either with weight loss measurements (ASTM A 262 – Method B, C, F and ISO 3651-1),<sup>10,29</sup> or by visual inspection of the exposed specimen surface after bending (ASTM A 262 – Method E and ISO 3651-2).<sup>10,30</sup> Bending tests only provide a qualitative measure of the IGC susceptibility, and these test environments are typically less aggressive. Metallographic sectioning can also be used for further susceptibility discrimination. Tests summarized in **Table 2** are all sensitive to intergranular chromium depletion, but individual tests also show sensitivities to chromium-rich phases, molybdenum-depletion around  $\sigma$ -phase, or other microstructural constituents, such as end-grains.

The oxalic acid test in **Table 2** is an electrolytic screening test, and is used for rapid assessment of cast and wrought austenitic (ASTM A262 – Method A)<sup>10</sup>

and ferritic (ASTM A763 – Method W)<sup>39</sup> stainless steels. The recommended current density and exposure time severely over-etch the microstructure, in order to facilitate a simple microstructure susceptibility classification.<sup>17</sup> The test reveals chromium depleted regions in the vicinity of sensitized boundaries or intermetallic phases.<sup>17</sup> Experiments with pure chromium have also indicated an attack of chromium rich phases,<sup>22</sup> making the oxalic acid test suitable for accepting resistant materials, but not for the rejection of susceptible material heats.<sup>17</sup> The oxalic acid test discriminates three different microstructure conditions comprising, (i) an IGC resistant step-like microstructure, (ii) a dual microstructure, containing a mixture of stepped and ditched grain boundaries, and (iii) a ditched structure, associated with deep, grain-surrounding etch trenches. **Figure 8** compares these classifications for a wrought austenitic stainless steel plate. The standard oxalic acid test yields only qualitative information, but quantitative information about the attacked grain boundary network can also be extracted. The extent of susceptible grain boundaries can be determined, for instance, by using the oxalic acid test in conjunction with image analysis methods, or with mean linear intercept procedures. These assessments can provide valuable information to quantify material susceptibilities.

**Table 2** ASTM and ISO practices for IGC testing of stainless steels<sup>10,29,30,39</sup>

<i>Standard</i>	<i>Test solution</i>	<i>Materials</i>	<i>Nature of attack</i>	<i>Duration/ temperature</i>

	(Method C) Ferric sulfate, 40% sulfuric acid	(C) Austenitic, ferritic, duplex SS #		20 $\pm$ 5 h/ boiling

\*Excluded from ASTM A262, # Material range defined in standards, SS = Stainless steel.

The ferric sulfate–sulfuric acid test is manifest in a broad range of standard procedures (such as ASTM A262 – Method B), and can be used to detect chromium depletion in austenitic, ferritic and duplex stainless steels (Table 2), as well as in nickel–chromium and nickel–chromium–molybdenum based alloys (Table 3). Generally, an increase in the sulfuric acid concentration from 10% to 60% significantly increases the corrosion rate in this test,<sup>17</sup> whereas the ferric sulfate functions as an inhibitor for stainless steel corrosion.<sup>17</sup> It is therefore recommended to regularly

replenish ferric sulfate, to maintain passive conditions and avoid excessive general corrosion.<sup>17</sup>

Nitric acid IGC tests, such as ASTM A 262 – Method C (Huey),<sup>10</sup> are highly oxidizing and attack chromium depleted regions, regions with segregated impurity or alloying elements, as well as exposed end grains. After deformation, attack at slip bands has also been reported.<sup>1</sup> Experiments with pure chromium also indicated that the nitric acid test readily attacks chromium rich phases.<sup>22</sup> The accumulation of hexavalent chromium ions, typically brought about by leaching out

**Table 3** ASTM and ISO practices for IGC testing of nickel-based alloys. (GB = Grain boundary/# Material range defined in standards)<sup>28,35</sup>

Standard	Test solution	Materials	Nature of attack	Duration/ temperature
ASTM G 28 (2008)	(Method A) Ferric sulfate, 50% sulfuric acid	Wrought + weldments; Ni-based, Cr-bearing alloys #	GB precipitates	24–120 h/ boiling
	(Method B) Sulfuric acid, hydrochloric acid, ferric chloride, cupric chloride	Wrought; Ni-base, Cr-bearing alloys #	GB precipitates	24 h/boiling
ISO 9400 (1996)	Method (A) Ferric sulfate, 50% sulfuric acid	Ni-based, Cr-based alloys #	GB precipitates	24–120 h/ boiling
ISO 9400 (1996)	Method (B) Copper, copper sulfate, sulfuric acid	Wrought + weldments; Ni-based, Cr-bearing alloys #	GB precipitates, excluding $\chi$ -, $\sigma$ -phase, TiC + TiN	$\geq 24$ h/boiling
	Method (C) Hydrochloric acid	High Mo-containing Ni and Ni–Cr base alloys #	GB Precipitates, Mo depletion	168 h/boiling
	Method (D) Nitric acid	Wrought; Ni-based, Cr-bearing alloys #	GB Precipitates, $\chi$ -, $\sigma$ -phase, TiC + TiN	$\geq 48$ h/boiling

from dissolved second phases, significantly increases the corrosion rate in this solution.<sup>17,22</sup>

The copper sulfate–16% sulfuric acid IGC test (Strauss) was initially recommended for the assessment of stainless steels with test durations of several hundreds of hours.<sup>17</sup> For accelerated testing, either metallic copper, or an increased concentration of sulfuric acid can be utilized.<sup>17</sup> Synergistic effects of the addition of higher concentrations of sulfuric acid and the contact to copper are utilized for IGC testing of cast stainless steels, such as ASTM A262 – Method F.<sup>10</sup> In sulfuric acid, cupric ions function as an inhibitor.<sup>17</sup>

The IGC resistance of stainless steels in mildly oxidizing solutions is a function of the chromium content, as shown in Figure 5.<sup>44</sup> An increase in the chromium content reduces the active–passive transition current density and enlarges the passive regions which makes passivation easier. In highly oxidizing solutions, such as boiling nitric acid, the presence of intermetallic phases and the segregation of solute atoms at grain boundaries also play a very important role. Annealed, nonsensitized stainless steels,<sup>2,45</sup> as well as pure nickel<sup>23</sup> and nickel alloys<sup>3</sup> have been found to undergo IGC in these highly oxidizing environments. Figure 9 gives a schematic summary of an anodic polarization curve for austenitic stainless steel in sulfuric acid with superimposed potential regions of the ASTM A 262<sup>10</sup> tests. The oxalic acid test is not shown, and would be located at a potential higher than the Huey test.

IGC tests for nickel alloys are summarized in Table 3. These tests are restricted to a range of alloy groups comprising alloy 600, alloy 625, alloy

800, alloy 825, and alloy C-276. A list of susceptible materials is given in the corresponding standard practices. Evaluation of the IGC susceptibility is carried out by visual examination after bending (ISO 9400 – Method B),<sup>28</sup> or with weight loss measurements. Additional metallographic examinations are generally recommended. It is also recommended to compare differences in the measurements of weight loss to material reference conditions, since variations in composition and thermomechanical process history may exert a large effect on determined corrosion rates. This is also reflected in differences in the recommended exposure durations, which vary with alloy composition (ASTM G 28).<sup>35</sup>

### 2.06.3.2 Microstructure Screening

Metallographic etching procedures can be used for rapid first principle assessments of IGC susceptibilities. This requires knowledge of individual microstructure constituents attacked by the metallographic etching procedure and, more importantly, whether there exists a relationship between these constituents and the real IGC behavior. For instance, a typical test for aluminum–magnesium alloys (5XXX) is the orthophosphoric acid etch. This etch highlights intermetallic  $\beta$ -phase ( $\text{Al}_3\text{Mg}_2$ ) precipitates, and has been used to gain information for exfoliation testing.<sup>42</sup>

### 2.06.3.3 Degree of Sensitization Testing

For characterizing the degree of sensitization, (i) the length of grain boundaries with chromium depletion, (ii) the width of the depleted zone, and (iii) the

**Figure 8** Optical micrographs of a Type 304 austenitic stainless steel after IGC screening in 10 wt% oxalic acid. Micrograph (a) shows a stepped, (b) a dual, and (c) a ditched microstructure.

minimum chromium concentration should be taken into consideration. For this purpose, a number of electrochemical test methods to quantify the degree of sensitization in stainless steels and nickel-base

**Figure 9** Schematic polarization curve of an austenitic stainless steel in deaerated sulfuric acid with superimposed potential regimes for the ASTM A 262 test methods. Potentials are given versus the normal hydrogen electrode (NHE,  $E_h$ ). Reproduced from Osozawa, K.; Bohnenkamp, K.; Engell, H.-J. *Corros. Sci.* **1966**, 6, 421–433.

alloys are available.<sup>20</sup> Electrochemical tests are typically considered to be more sensitive for measuring the whole spectrum of sensitization, including lightly to severely sensitized materials. A saturation of the discriminating power, however, has been reported at high degrees of sensitization.<sup>46</sup> IGC tests based on weight loss or surface fracture measurements (i.e., [Tables 2 and 3](#)) are more sensitive to medium and high degrees of sensitization, but can generally not discriminate low to medium degrees of sensitization.

Three electrochemical test methods are typically used for the assessments of the degree of sensitization, as summarized in [Table 4](#). These test comprise (i) the electrochemical reactivation (EPR)<sup>37</sup> test, (ii) the double-loop electrochemical potentiokinetic reactivation (DL-EPR)<sup>47</sup> test, and (iii) Cihal's DL-EPR<sup>31</sup> test. All tests are based on similar principles, but differ in the way the data are analyzed. [Figure 10\(a\)](#) shows EPR curves for a sensitized and non-sensitized stainless steel and [Figure 10\(b\)](#) shows a DL-EPR curve for a sensitized stainless steel with characteristic parameters. All three methods for quantifying the degree of sensitization are based on measuring the reactivation current density ( $i_{\text{reactivation}}$ ) in a solution of sulfuric acid and thiocyanate. The thiocyanate functions as a

**Table 4** Methods for detecting and quantifying the degree of sensitization in stainless steels and nickel alloys<sup>31,37,47</sup>

Method	Test solution	Materials	Assessments
ASTM G 108 (2004)	0.5 M Sulfuric acid + 0.01 M KSCN	Type 304/Type 304L	$Q_{\text{reactivation}}$ and $i_{\text{reactivation}}$ ( $Q_{\text{reactivation}}/\text{GB area}$ )
-EPR Test-			
ISO 12732 (2006)	0.5–2.5 M Sulfuric acid + 0.001–	Stainless steels	Ratio = ( $i_{\text{reactivation}}/i_{\text{anodic}}$ )
-Cihal's DL-EPR Method-	0.05 M KSCN	Nickel alloys	Ratio = ( $i_{\text{reactivation}}/\text{GB area}$ )/ ( $i_{\text{anodic}}/\text{Specimen area}$ )
			Ratio = ( $Q_{\text{reactivation}}/\text{GB area}$ )/ ( $Q_{\text{anodic}}/\text{Specimen area}$ )
DL-EPR	0.5 M Sulfuric acid + 0.01 M KSCN	Type 304	Ratio = ( $i_{\text{reactivation}}/i_{\text{anodic}}$ )

GB = Grain boundary,  $i_{\text{reactivation}}$  = Maximum reactivation current density,  $Q_{\text{reactivation}}$  = Reactivation charge density,  $Q_{\text{anodic}}$  = Anodic charge density.

**Figure 10** (a) Schematic diagram of an EPR test for sensitized (curve a) and non-sensitized (curve b) stainless steel. (b) Schematic diagram of a DL-EPR test with characteristic parameters. ( $E_{\text{Corr}}$  = corrosion potential,  $i_{\text{anodic}}$  = maximum anodic current density,  $i_{\text{reactivation}}$  = reactivation current density,  $Q$  = charge density.)

depassivator, and increases the anodic dissolution during the anodic sweep, as well as the grain boundary attack during the reactivation sweep.<sup>47</sup> On sensitized material, the breakdown of the passive film on chromium depleted areas leads to the reactivation peak, but on nonsensitized material, the passive film remains

virtually intact, and either no or only a small increase in reactivation current density is observed. The maximum height ( $i_{\text{reactivation}}$  – current density) and area ( $Q$  – charge density) under the reactivation curve is a quantitative measure of the degree of sensitization (Figure 10).

The EPR test is a standard test method (ASTM G 108),<sup>37</sup> often referred to as the single-loop EPR test (SL-EPR). Evaluation of the degree of sensitization is carried out after an initial passivation treatment (+0.2 V<sub>SCE</sub> for 2 min), by measuring the maximum reactivation current ( $i_{\text{reactivation}}$ ) or charge density ( $Q$ ). The reactivation charge density can also be normalized to the grain size, and gives a measure of attacked grain boundary area. After testing, the specimen has to be examined under an optical microscope, to determine whether the measured reactivation current is derived from chromium depleted regions at the grain boundaries, and not from intragranular pitting. A major drawback of this test is its sensitivity to material composition, thermomechanical process history, surface finish, and nonmetallic inclusions.<sup>37</sup>

An advanced version of the EPR tests is the double-loop technique (DL-EPR)<sup>47</sup> for Type 304 stainless steels. This test has frequently been used due to its ease of application. The degree of sensitization is determined with the maximum reactivation current density ( $i_{\text{reactivation}}$ ) divided by the maximum anodic current density ( $i_{\text{anodic}}$ ), without assessment of the grain boundary area. For an improved correlation between results derived from the DL-EPR and the EPR test, however, it is recommended to normalize the reactivation current density by the grain boundary area.<sup>47</sup> The DL-EPR test is not sensitive to the surface finish of the specimen, since the anodic sweep causes a general dissolution of the test surface.

A modified version of the DL-EPR test, based on Cihal's method, has been incorporated as a standard test method (ISO 12732).<sup>31</sup> This test is applicable for a broad range of stainless steels, including supergrades, as well as for certain nickel-base alloys. For this purpose, the sulfuric acid and thiocyanate concentrations can be tailored (Table 4). The assessment of Type 304 stainless steel is carried out with the same test parameters and solution concentrations as used for the EPR and DL-EPR tests. Cihal's test is assessed with the ratio of the reactivation current density, divided by the grain boundary area, and the maximum anodic current density, divided by specimen area. This accounts for a general dissolution of the surface during the anodic sweep, in relation to the dissolution of the sensitized grain boundary area during the reactivation sweep. The same assessment can also be carried out by using the charge densities instead of current densities. For comparing sensitized materials with similar grain sizes, the ratio between the maximum reactivation current density ( $i_{\text{reactivation}}$ ) and the maximum

anodic current density ( $i_{\text{anodic}}$ ) can also be employed, similar to the DL-EPR test.<sup>47</sup> A comparison of typical values for the EPR, DL-EPR, and Cihal's test is given in corresponding literature sources.<sup>31,47</sup>

## 2.07.1 Introduction

Galvanic corrosion, also known as bimetallic corrosion, is a common mode of corrosion failure that is, for the most part, entirely preventable by proper corrosion design. It is the aim of this chapter to provide the reader with the knowledge and data to aid in recognizing this form of corrosion when it occurs and making the right design decisions to prevent it.

The ASTM International Committee G01 on Corrosion of Metals defines galvanic corrosion as “accelerated corrosion of a metal because of an electrical contact with a more noble metal or nonmetallic conductor in a corrosive environment.”<sup>1</sup> NACE International defines galvanic corrosion as “corrosion associated with the current resulting from an electrical coupling of dissimilar electrodes in an electrolyte.”<sup>2</sup> International Organization for Standards (ISO) defines galvanic corrosion as “Corrosion due to the action of a corrosion cell [a short-circuited combination of different electrodes connected in

series with an ionic conductor].”<sup>3</sup> Other organizations that have definitions for galvanic corrosion include The Electrochemical Society, the American Water Works Association, The American Chemical Society, and others. What these definitions all have in common is that galvanic corrosion involves the electrical interaction of at least two different metals or nonmetallic conductors in an environment that accelerates the corrosion of at least one of them. The common factors are dissimilar metals, electrical contact, and a conductive electrolyte in contact with them. If any of these factors is absent, galvanic corrosion cannot occur.

Galvanic corrosion accelerates the normal corrosion of a metal in an electrolyte. Even without galvanic corrosion, metals may suffer from uniform corrosion, crevice corrosion, pitting, or other forms of corrosion. Galvanic corrosion has an accelerating effect on these other forms of corrosion and, in some cases, causes a form of corrosion to occur that would otherwise not be seen.

## 2.07.2 Electrochemical Theory

When a metal or nonmetallic conductor is immersed in a conductive solution, or an electrolyte, a series of reactions takes place that can cause corrosion. The corrosion reaction itself involves a change in the charge of the metal atoms from zero in the metal to a positive value for metal ions in the solution. Because this is a positive change in charge the reaction is called an anodic reaction and can be written as:

where M = some metal atom or ion, and  $n$  is a number typically between 1 and 3 depending on the metal and electrolyte.

Since this reaction generates free electrons and since charge neutrality must be maintained, these electrons must be used up in one or more other reactions where charge is reduced in order for corrosion to proceed. These are called cathodic reactions, and the most common ones found in aqueous environments are:

The progression of the anodic and cathodic reactions, the flow of electrons, and the ionic motion in the electrolyte needed to complete the current flow are

shown in **Figure 1** for a piece of iron corroding in neutral water.

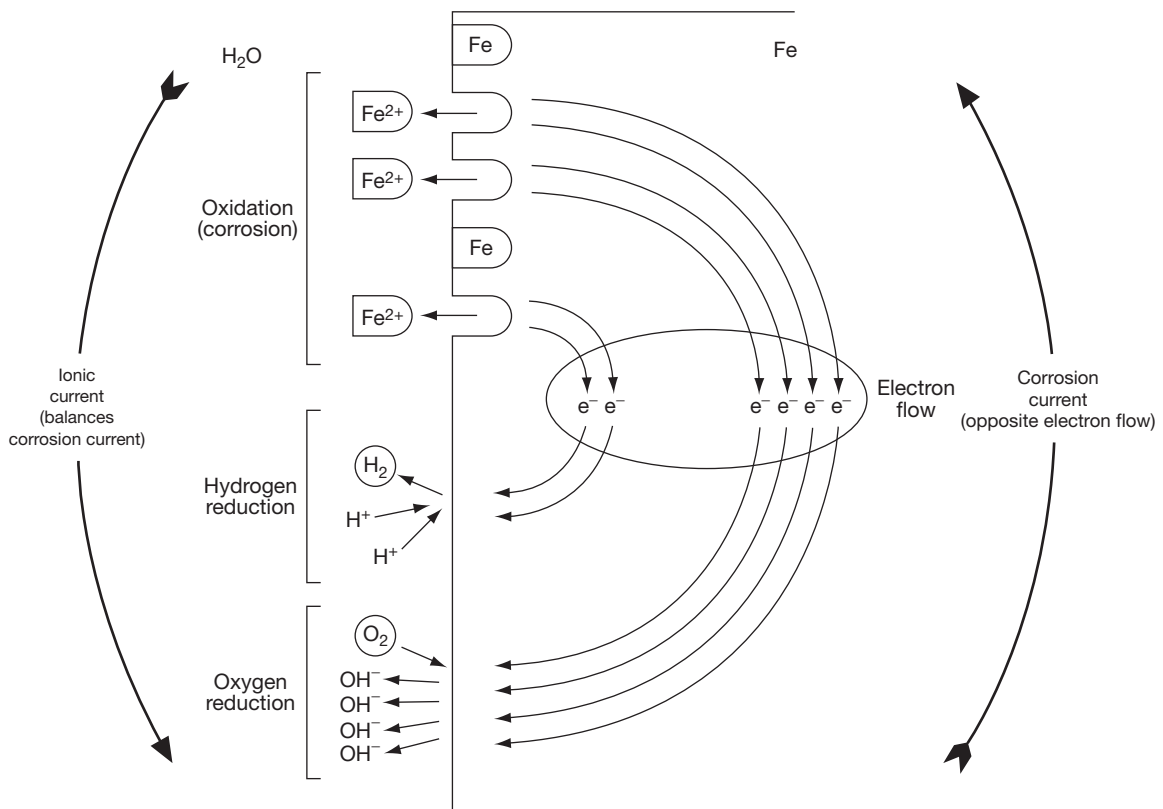

Corrosion cannot proceed unless all of the electrons generated by the anodic reaction are used up by a cathodic reaction. The balance between these two reactions leads to each metal, alloy, or nonmetallic conductor equilibrating at an electrochemical potential that is unique to that material and electrolyte, called the corrosion potential. For a given electrolyte, the corrosion potential of a number of materials can be listed together. Such a listing, where the materials are arranged according to ascending or descending corrosion potential, is called a galvanic series. If two materials with different corrosion potentials are immersed in that electrolyte and electrically coupled, there is a driving force for a current, called the galvanic current, to flow between them. It is this flow of current that increases corrosion of the material with the more negative potential, called the anode, while suppressing the corrosion of the more positive material, called the cathode.

The most common galvanic series is the one shown in **Figure 2** for metals in seawater. Metals

with more negative corrosion potentials are said to be anodic compared to metals with more positive, or cathodic, potentials in a galvanic series.

In this case, the corrosion potentials are given as ranges, since seawater composition can vary and since corrosion potentials can be influenced by the presence of corrosion products on the surface of the corroding metal. Some metals show two bands of corrosion potentials, one in white and the other in black. These are metals that can exist in two different states in seawater, a passive state during which they are not corroding and an active state when they are corroding. Each state is associated with a different range of corrosion potentials. This galvanic series is only applicable in seawater at a specific temperature range and flow rate, and should not be applied to other environments.

Galvanic series are useful to predict which metal in a pair of electrically connected materials in an electrolyte, called a galvanic couple, will tend to have its corrosion rate accelerated by the electrical contact. The fact that there is a driving force for current to flow between the dissimilar materials and

**Figure 1** Iron corroding in water. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

**Figure 2** Galvanic series for metals in seawater with moderate flow. Reproduced from Standard G82: Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance, *ASTM Book of Standards*; ASTM International: West Conshohocken, PA, 2006.

for the corrosion of the anode in the couple to increase does not mean, however, that the magnitude of this current and resulting corrosion will be significant.

When two dissimilar materials with dissimilar corrosion potentials are coupled in an electrolyte, they will each be forced to a common potential somewhere between the two individual corrosion potentials. When coupled, materials with similar corrosion potentials have no driving force for causing galvanic corrosion. However, materials far apart in potential will not necessarily result in higher galvanic corrosion rates than materials close together in potential. The magnitude of current flow and the increase in corrosion rate due to this coupling are determined by the tendency of each of the materials in the couples to deliver current when its potential is forced to change, called polarization. If a material delivers little current for a large change in potential, it is said to have a large polarization resistance, while if it can deliver a large current for a small enforced potential change, it is said to have a small polarization resistance. This is illustrated by plotting the current produced as a function of applied potential, called a polarization curve. Examples of polarization curves for metals with high and low polarization resistances are shown in Figure 3. In this figure, when the cathode has low polarization resistance and the anode has high resistance, the couple is said to be under cathodic control. When the reverse is the case, the couple is said to be under anodic control, and when the polarization resistances of the anode and cathode reactions are similar the couple is said to be under mixed control.

When two materials are coupled in an electrolyte, the galvanic current flowing between them is determined by a superposition of the cathodic polarization curve of the anodic metal with the anodic polarization curve of the cathodic material, shown in Figure 4. In this figure,  $I_{\text{measured}}$  is the galvanic current that flows through the metallic path between the two metals, in this case copper and iron.

The magnitude of the galvanic current flowing in a galvanic couple gives a qualitative feel for the amount of increased corrosion of the anode, but it is not a good quantitative measure. To understand why this is so, it is necessary to look at the magnitude of the anodic and cathodic reactions that are occurring on each metal in the couple, both before the metals are electrically connected and afterwards. To understand corrosion rates in a galvanic couple, it is necessary to look at a plot of individual reaction

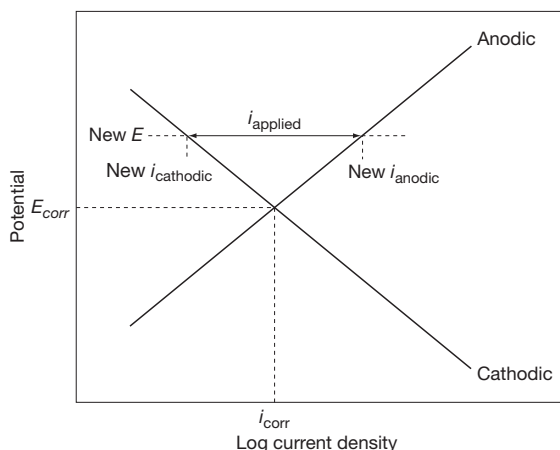

**Figure 3** Effect of polarization resistance on anode and cathode reactions. Reproduced from Standard G82: Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance, *ASTM Book of Standards*; ASTM International: West Conshohocken, PA, 2006.

**Figure 6** Relationship between a forced potential shift and applied current. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

rates as a function of potential, called an Evans diagram, for each of the materials in the couple before they are coupled (Figure 5). This figure shows the cathodic reaction to be hydrogen production, but any cathodic reaction, such as oxygen reduction, would behave similarly. The corrosion rate for iron in this diagram is  $i_{\text{corr}}$  and the corrosion potential is  $E_{\text{corr}}$ .

The rate of the anodic reaction increases as the potential becomes more positive, while the rate of the cathodic reaction increases as the potential becomes more negative. The net current flowing to or from the metal is the difference between these two

currents, or zero at the point where the two curves cross. Applying a current will force a potential shift to occur, as shown in the Evans diagram in Figure 6.

When two materials are coupled, the Evans diagrams for them are shown in Figure 7.

For two materials in electrical contact, the sum of all anodic reactions must equal the sum of all cathodic reactions. Where the anodic sum crosses the cathodic sum determines the potential of the galvanic couple, called the coupled potential. Once this potential is known, the rates of all reactions on both materials are read from the Evans diagram for each reaction at that coupled potential. This coupled potential can also be obtained from polarization curves, as shown in Figure 4. Figure 8 shows the polarization curves on an Evans diagram so that the relationship can be seen. The galvanic current from the polarization curves is the actual measurable current that flows between the two materials, but is not necessarily directly related to the corrosion rate of the anode.

In practice, it is difficult to determine the exact position of all reaction curves on all materials, particularly in complex environments like seawater. For this reason, it is more common to determine corrosion rates for galvanic corrosion by first determining the coupled potential using polarization curves, and then testing the anode material by holding it at that potential and measuring the actual corrosion rate experienced.

All the Evans diagrams and polarization curves for galvanic couples shown above have used either current density or total current on the horizontal axis, assuming that the exposed surface areas of the anode and cathode metals are the same. The effect of different exposed surface areas of the anode and cathode materials can be examined by realizing that the total current is just the current density multiplied by the exposed surface area. Larger exposed areas will shift the polarization curves to the right for that material. The effect of this on coupled potential and galvanic current is shown in Figure 9.

This leads to the conclusion that to minimize galvanic corrosion small cathode–anode area ratios are required, or conversely the larger this ratio, the larger is the galvanic corrosion. This is sometimes called the catchment area principle. For this reason, to control galvanic corrosion it is best to paint the noncorroding cathode, not the corroding anode, contrary to what might be inferred at first glance.

Polarization does not always take the form of straight lines on Evans diagrams. Real polarization

**Figure 7** Evans diagram for two materials in electrical contact. Reproduced from Standard G82: Guide for Development and Use of a Galvanic Series for Predicting Galvanic Corrosion Performance, *ASTM Book of Standards*; ASTM International: West Conshohocken, PA, 2006.

**Figure 8** Polarization curves on an Evans diagram. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

curves are affected by the formation of corrosion products and the ability of reactants and reaction products to move to and from the surface where the reactions take place. This leads to various polarization curve shapes, including some that curve back on themselves, as shown in [Figure 10](#).

Galvanic reactions with materials having these types of curves can lead to some unusual corrosion

consequences, including having several different stable corrosion potentials for a given galvanic couple, as seen in [Figure 11](#).

If more than two materials with different corrosion potentials are electrically connected, they can be analyzed using the same principles as when two materials are analyzed, that is, using Evans diagrams. The anode and cathode reaction curves for all three materials are normalized to the proper surface areas and then put on the same diagram, together with the total anodic and total cathodic curves. Then the intersection point of latter curves defines the coupled potential. From this coupled potential the corrosion rate of all three materials can be determined.

Galvanic corrosion can also be affected by electrical or ionic resistances between the two coupled materials. Electrical resistance can come about if one of the materials is a poor electrical conductor or if the contact between them is not made properly. Ionic resistance occurs because electrolytes are not perfect conductors, so that high electrolyte resistivity coupled with a large distance between the anode and cathode materials can lead to significant resistance between the anode and cathode. Electrical and ionic resistance are treated the same when determining their effect on a galvanic couple. The total circuit resistance is the product of the galvanic current and the various resistances, frequently called *IR* drop. The effect of *IR* drop is seen in [Figure 12](#).

**Figure 9** Effect of area ratio on superimposed polarization curves. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

**Figure 10** Polarization curve for passive-film-forming metal such as 430 stainless steel in sulfuric acid. Standard G3: Practice for Conventions Applicable to Electrochemical Measurements in Corrosion Testing, *ASTM Book of Standards*; ASTM International: West Conshohocken, PA, 2006.

**Figure 11** Triple crossing of anodic and cathodic polarization curves leading to two stable corrosion potentials.

**Figure 12**  $IR$  drop leading to anode and cathode being at different potentials. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

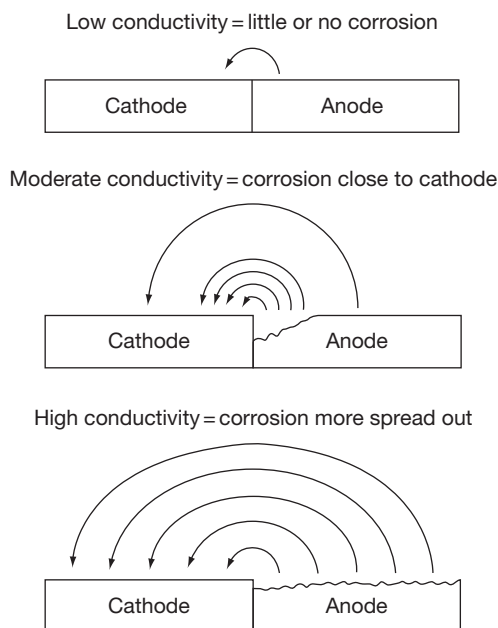

$IR$  drop leads to the anodic and cathodic materials being at different potentials, with the associated lowering of corrosion rate of the anode from the value if there were no resistance. Low galvanic currents lead to low  $IR$  drop, so this effect is more pronounced on large structures. Also, larger distances between anode and cathode lead to larger  $IR$  drops, and therefore

lower galvanic corrosion rates. For this reason, in galvanic couples that are large or where electrolyte resistance is high, galvanic corrosion rates are highest on the anode closest to the cathode and drop off as distance between anode and cathode increases. This falloff in corrosion rate with distance is one good method for identifying galvanic corrosion, although if conductivity is high or distances are small this dropoff effect may not be observed. This can be seen in [Figure 13](#).

### 2.07.3 Examples of Galvanic Corrosion

One typical example of galvanic corrosion is the use of dissimilar metal fasteners. When the fastener is anodic compared to the structure that it is fastening, the anode-to-cathode ratio is large and the fasteners will corrode quickly. When the fastener is cathodic compared to the structure the anode-to-cathode ratio is small and the corrosion acceleration of the structure around the fasteners is present but minimal as long as the electrolyte conductivity is high, as seen in [Figure 14](#).

Galvanic corrosion also commonly occurs in the attachment of dissimilar metal piping. Here,

**Figure 13** Concentration of corrosion near cathode as a function of conductivity. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

**Figure 14** Corrosion of fasteners and base plate in relation to the anode.<sup>6</sup> (a) Base plate is the anode in high-conductivity water; (b) base plate is the anode in low-conductivity water; (c) fastener is the anode.

corrosion of the more anodic pipe will be concentrated at the junction with the cathode.

Structures made from dissimilar metals are sometimes joined in soils. This can be inadvertent, such as when a section of pipe is replaced with a new piece of

pipe, not realizing that the new pipe is frequently cathodic to the old pipe. The new pipe will therefore cause the old pipe to corrode faster.

Sometimes in a mixed-metal structure one part that corrodes quickly will be 'upgraded' to a more corrosion-resistant material. Steel may be replaced with stainless steel, stainless steel with nickel alloys, etc. The more corrosion-resistant material is frequently cathodic to the other materials in the structure, causing galvanic corrosion of the structure close to the parts that were replaced. This makes it look like the corrosion problem is moving around the structure, while it is in fact due to lack of attention to galvanic corrosion in design of the replacement material.

Tube-tubesheet heat exchangers frequently use different materials for the tubes than for the tube-sheet, support structure, or shell. This can lead to galvanic corrosion of any of these parts, depending on the particular material combinations chosen.

## 2.07.4 Benefits of Galvanic Corrosion

Galvanic corrosion can be beneficial. The potential and current between dissimilar metals is used in a sensor for time of wetness in atmospheric corrosion testing.<sup>7</sup> When rainwater or dew is present on the sensor, a galvanic couple exists, whereas when the moisture is not present the galvanic couple is not active. Similar sensors can be buried inside lap joints or other hard-to-access areas and can be used to determine whether sufficient moisture is present for corrosion to occur where it cannot be seen.

Special materials that can generate high galvanic corrosion currents have been prepared in powder form. When wetted, these powders result in galvanic corrosion rates that are so high that significant heat is generated. This is how meals for the U.S. Armed Forces, called MREs (meals ready to eat), are heated in the field: just add water to get a hot meal.

There are other benefits to high galvanic corrosion rates. Special corrodible pins, consisting of a hollow anode with a cathode on the inside, have been produced in a way that the failure time for the pin is well characterized. Such pins are used in seawater to keep crab and lobster pot buoys submerged to prevent poaching for a given time period, after which the buoys are released by corrosion of the pin and the pots can be retrieved by their owners. A similar system is used to cause military sonobuoys,

used to detect enemy submarines, to sink after their useful lifetime is exhausted. A corrodible plug is used for this purpose to allow flooding of the buoy after a known period of time.

Galvanic corrosion is the basis for the operation of most batteries. The galvanic current produced by the couple is put to good use in our toys, cell phones, and other electronic hardware.

Finally, the cathode in a galvanic couple frequently has its corrosion rate decreased as a result of the couple. This is the basis for sacrificial anode cathodic protection used widely in seawater and soils to protect steel structures. By coupling the steel to a piece of anodic material such as zinc, aluminum, or magnesium, the accelerated corrosion of the anode causes corrosion of the steel to be reduced. The anode sacrifices itself to prevent corrosion of the steel and is periodically replaced as it is consumed.

### 2.07.5 Recognizing Galvanic Corrosion

There is no absolutely certain method of determining that corrosion seen on a structure is actually galvanic corrosion, since the action of galvanic corrosion is usually to accelerate the type of corrosion normally experienced by the anode material. There are clues, however, that can help to make the determination. Galvanic corrosion always involves two materials with different corrosion potentials electrically connected in a common electrolyte. Therefore, if two materials with different corrosion potentials are present in the system and they are electrically connected in a common electrolyte, this is a strong clue that the corrosion that is observed is galvanically accelerated. This is particularly true if the anodic material has a small surface area compared to the cathodic material and the two different materials are close together. If both materials are corroding, then this corrosion is unlikely to be galvanically accelerated.

There is one good indicator for galvanic corrosion, however. If the anodic material corrodes the fastest near the cathodic material, and if the amount of corrosion lessens as distance increases from the cathode, galvanic corrosion is the likely cause. For example, if a flange connects two dissimilar metal pipes and the metal with the more negative corrosion potential is corroding a lot near the flange and less far away from the flange, galvanic corrosion is indicated. Thickness loss of the anodic metal near

dissimilar metal lap joints or fasteners is likely to be due to galvanic corrosion. Some examples of galvanic corrosion are shown in [Figures 15–18](#).

### 2.07.6 Predicting Galvanic Corrosion

When designing a structure it is important to take into account galvanic corrosion either by preventing it or by predicting where it will occur and how much metal will be lost over time so that structure lifetime can be determined and maintenance activities can be planned accordingly. The methods used to predict galvanic corrosion include experience with similar materials and geometries in similar environments, use of exposure data in similar environments, use of laboratory test data, computer modeling, physical scale

modeling, and numerical calculations such as Wagner number. Each of these will be discussed below.

### 2.07.6.1 Experience

The best way to predict galvanic corrosion is to rely on experience with similar materials in similar geometries under similar environmental conditions to those of the structure being predicted. If you are designing a power plant condenser, experience with other power plant condensers is most useful, whereas if you are designing a metal roof system for a building, experience with similar roofing systems is the most valuable information to use. Locating data for the exact materials, the exact geometry, and the same environment can be difficult or impossible, in which case prediction must be based on another method.

### 2.07.6.2 Exposure Data

When the exact geometry cannot be found, exposure data from similar materials in a similar environment to that of interest can be used instead. The geometrical effects of area ratio and proximity of dissimilar materials can usually be accounted for in a qualitative fashion, while computer modeling can sometimes be used to get more quantitative predictions. Besides

selecting data from the same materials as those of interest, the most important test variable to consider is the environment. Galvanic corrosion can be very different in atmospheric environments, immersion in seawater or other chemicals, soils, inside concrete (such as reinforcing bar), etc. Even for atmospheric exposure, many variables can affect corrosion such as industrial versus rural, proximity to the sea, rainfall, humidity, amount of sunshine, and geometrical effects such as angle of exposure and shielding by neighboring structures.

### 2.07.6.3 Laboratory Data

Small-scale exposures of specimens in the laboratory can sometimes yield valuable information needed to predict galvanic corrosion. Laboratory tests can generate data on corrosion potentials, polarization behavior, and galvanic currents for specific geometries. Information regarding how to measure corrosion potentials and generate a galvanic series in a specific environment is given in a standard guide from ASTM International.<sup>5</sup> There are probably as many ways to generate polarization curves as there are investigators, but a good place to start is by generating either a potentiodynamic scan or a series of potentiostatic tests. Potentiostatic tests can also give a measure of the amount of corrosion of a metal as a function of its potential. Methods for conducting these tests are beyond the scope of this chapter.

Once corrosion potentials are known for the materials of interest in the environment of interest, classification of the material as an anode or a cathode can be made. Superposition of a cathodic polarization curve of the anode metal with an anodic polarization curve of the cathode material, with suitable scaling for relative surface areas, can generate information on the potential of the couple. Assuming no  $IR$  drop, this potential is the potential of both of the materials in the couple. Using potentiostatic corrosion rate data at this potential, the corrosion rate of the anode can be determined. This process of predicting galvanic corrosion rate from laboratory data is shown in [Figure 18](#).

### 2.07.6.4 Computer Modeling

Computer modeling, specifically boundary element modeling and to a lesser extent finite element modeling, can be used to predict the amount and distribution of galvanic corrosion on a complex structure. The computer requires input of a detailed geometrical

**Figure 18** Predicting galvanic corrosion rate from potentiostatic data. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

model of all surfaces exposed to the environment, the ionic conductivity of the environment, and the polarization curves for all of the materials involved. The latter is the most difficult data to obtain, since in many real situations polarization curves vary as a function of time and potential. Nevertheless, some excellent modeling has been conducted for large structures in seawater, mostly related to sacrificial anode cathodic protection (the opposite of galvanic corrosion) but to a lesser extent to galvanic corrosion.<sup>8-21</sup> Examples are shown in [Figures 19 and 20](#).

### 2.07.6.5 Physical Scale Modeling

Physical scale modeling of complex structures has also been used to predict the amount and distribution of galvanic corrosion and cathodic protection.<sup>22-25</sup> Known by some investigators as dimension and conductivity scaling (DACS), proper scale modeling of corrosion processes involves increasing the resistivity of the environment by a factor equal to the dimensional scale factor. For example, a 1:10 scale model

must be tested in an environment that has 10 times the resistivity of the full-scale environment, as seen in [Figure 21](#).

### 2.07.6.6 Wagner Number

The Wagner number is the ratio of the polarization resistance of the materials of interest to the resistivity of the environment, expressed as the slope of a polarization curve.<sup>12,26,27</sup> It can be expressed as

$$W = (dE/di)/R \quad [1]$$

where  $dE/di$  is the local slope of the polarization curve of the metal of interest and  $R$  is the resistivity of the electrolyte.

If the Wagner number is large, galvanic current will flow far from the interface between anode and cathode, whereas if the Wagner number is small galvanic current will be more localized near the joint. Thus, large Wagner numbers are indicative of uniform distribution of galvanic corrosion, while

**Figure 19** Computer-predicted potential distribution on a 48-ft barge with sacrificial anodes (half model). Reproduced from Hack, H. P.; Janeczko, R. M. Verification of the boundary element modelling technique for cathodic protection of large ship structures, CARDIVNSWC-TR-61-93/02, Naval Surface Warfare Center Carderock Division, Bethesda, MD, December 1993.

**Figure 20** Computer prediction of potential profiles on cathodically protected K joint on offshore oil platform. Reproduced from Adey, R. A.; Niku, S. M. In *Galvanic Corrosion*; Hack, H. P. Ed.; ASTM International: West Conshohocken, PA, 1988; ASTM STP 978, pp 96-117.

small Wagner numbers indicate localized galvanic corrosion. The effect of Wagner number is shown in [Figure 22](#).

### 2.07.7 Prevention

There are several ways to minimize or prevent galvanic corrosion. These include design changes, electrical isolation, electrical insulation, exclusion of the environment, increasing  $IR$  drop, anode-to-cathode area ratio control, corrosion inhibitors, cathodic protection, and counter-current devices. Each of these corrosion control methods seeks to reduce or eliminate one of the requirements for galvanic corrosion to occur: materials with dissimilar corrosion potentials, metallic pathway, and ionic pathway.

Design changes can be made to minimize or eliminate contact of dissimilar metals. One such change is the use of a galvanic strip, shown in [Figure 23](#). Use of this strip forces the dissimilar metal contact to occur in a metallurgically bonded transition material where water has limited access.

Electrical isolation eliminates galvanic corrosion by removing the metallic pathway between the dissimilar materials. This is usually accomplished with nonconductive spacers, gaskets, washers, and sleeves.

**Figure 21** Calculations to scale dimensions and conductivity for a galvanic couple.

**Figure 22** Effect of Wagner number on galvanic current distribution down an anodic tube. Reproduced from Scully, J. R.; Hack, H. P. In *Galvanic Corrosion*; Hack, H. P., ED., ASTM International: West Conshohocken, PA, 1988; ASTM STP 978, pp 136–157.

Typical methods for providing electrical isolation in a bolted joint are illustrated in [Figure 24](#).

Commercial isolation devices are also available for pipelines from several manufacturers. The material that is used for isolation must be electrically nonconductive, so carbon-bearing rubbers cannot be used. It does not matter whether the isolation material absorbs electrolyte, so it can be porous. Typical isolation materials include Acetal, glass-reinforced plastic, Mylar, and polyethylene. Many nonmetallic bearing materials provide electrical isolation automatically

for rotating equipment. Providing electrical isolation for complex structures is extremely difficult. Many isolator pieces are usually used, and unintentional shorts are difficult to control. Such unintentional shorts include pipe hangers, ground wires for electrical equipment, machining burrs, and inadvertent movable equipment like screwdrivers or steel wool pads. When providing electrical isolation it is imperative to check that electrical conductivity has been eliminated after assembly and periodically thereafter. Such checks must be done with the equipment dry.

**Figure 23** Use of a bimetallic transition material to minimize galvanic corrosion between low carbon steel (LCS) and aluminum. Reproduced from Baboian, R.; Haynes, G.; Turcotte, R. In *Galvanic Corrosion*; Hack, H. P., Ed.; ASTM International: West Conshohocken, PA, 1988; ASTM STP 978, pp 249–259.

Insulation is different in that the intent is not to remove the metallic pathway but instead to provide spacing between the anode and cathode to increase the resistance of the ionic pathway. This is commonly used in high-resistivity environments such as atmospheric exposure, where a small increase in spacing will have a large effect on ionic resistance. For this reason, plastic spacers are frequently used between stainless steel fasteners and aluminum siding material. Another application of this principle is the use of nonmetallic spool pieces to separate dissimilar metals in piping systems. Although the dissimilar metals may still be in metallic contact through supporting structure, the spool piece provides ionic resistance which lowers the amount of galvanic corrosion, and also causes the corrosion to be less localized on the anode pipe near the cathode.<sup>28</sup>

Galvanic corrosion can also be stopped by excluding the environment from the anode, the cathode, or both. This has sometimes been done successfully with the use of paint; however, paint systems will

**Figure 24** Designs for insulating joints to avoid corrosion likely if the fastener is anodic to the plate<sup>1</sup>: (a) bolt and plates are of different alloys (not ideal; see text); (b) the bolt is the same alloy as the lower plate; (c) same as (a) with insulating sleeve on bolt shank; (d) bolt and plates are all of different alloys; (e) suitable only for atmospheric or occasionally wetted surface. Courtesy of HMSO. Reproduced from Francis, R. *Galvanic Corrosion: A Practical Guide for Engineers*; NACE: Houston, TX, 2001.

develop defects over time which must be accounted for. Water-excluding greases, silicone sealants, and heavy nonmetallic linings will work for various periods of time, until they wash out or deteriorate enough to absorb electrolyte. It is safest to exclude the environment from the cathode, since this will eliminate the driving force for the galvanic corrosion.

Anything that increases the resistance of the ionic path between anode and cathode will reduce the rate of galvanic corrosion. Reducing electrolyte conductivity, increasing anode-to-cathode spacing, and providing nonmetallic barriers in the electrolyte between the anode and cathode are effective corrosion control methods.

Since the magnitude of galvanic corrosion is a function of the ratio of the wetted surface areas of the cathode to the anode, reducing this ratio will reduce galvanic corrosion. Masking of the cathode with paint can be highly effective, whereas painting of the anode alone must never be done. Area ratio control is most effectively done during the design phase of a structure. For example, fasteners should

be cathodic to the materials they fasten. When putting stainless steel fasteners through aluminum for seawater use, there are surface treatments that will make even this small area of noble material appear even smaller by masking the corrosion potential of the fastener. Such treatments include galvanizing, cadmium plating, and the use of a proprietary fastener treatment called Alumizite.

Corrosion inhibitors can control galvanic corrosion either by acting directly to prevent corrosion of the anode, called anodic inhibitors, or by increasing the polarizability of the cathode to lower its driving force on the anode, called cathodic inhibitors. Inhibitors that do both are called mixed inhibitors. If an anodic inhibitor is used, the coupled potential will shift in the cathodic direction, whereas a cathodic inhibitor will cause the coupled potential to shift in the anodic direction. Automobile cooling systems contain a variety of materials, including steel, copper alloys, and aluminum, all in direct metallic contact in a common electrolyte, the antifreeze/coolant. For this reason, companies that produce antifreeze/coolants have developed a suite of corrosion inhibitors that are highly effective at controlling galvanic corrosion in automobile engines, provided they are changed out every few years to replenish the inhibitors.

Cathodic protection of a structure will eliminate galvanic corrosion since it provides electrodes that are anodic to both materials in the galvanic couple. This is true for both sacrificial and impressed current cathodic protection systems. The one caution regarding this is that the normal corrosion of aluminum in seawater cannot be prevented by cathodic protection, and over-protection will cause considerable damage to the aluminum. Therefore, when trying to prevent galvanic corrosion of aluminum caused by contact with other materials, just enough cathodic protection should be used to polarize the other materials to the corrosion potential of the aluminum. The cathodic protection system must have an ionic path to all cathodes in the galvanic couple to be effective. Since cathodic protection cannot reach into faying surfaces, it is usually good practice to use nonconductive, nonporous spacers between dissimilar metals so protected, not to provide isolation but to force any potential galvanic currents to travel outside of the faying surface area where they can be mitigated by the cathodic protection system. A typical insulation scheme for faying surfaces uses two layers of MIL-I-24391 tape<sup>29</sup> with a total thickness of 0.43 mm (0.017 in.).

Counter-current devices are relatively new to the field of galvanic corrosion control. Their principle is

that they generate an *IR* drop in the electrolyte counter to the *IR* drop generated between the anode and cathode in a galvanic couple. This effectively prevents current from flowing in the electrolyte, stopping the galvanic corrosion. To date, one such device, called a bielectrode, has been the subject of research<sup>30–33</sup> and patents.<sup>34</sup> The galvanic couple geometry that can be controlled with this technology must be well controlled, and control of the counter current is the most difficult part of designing such a system. The principle of a counter-current device is shown in [Figure 25](#).

### 2.07.8 Testing

Galvanic corrosion testing is a complex subject that is discussed in detail elsewhere.<sup>4,35–39</sup> This chapter provides only a summary.

#### 2.07.8.1 General Principles

In general, when conducting tests for galvanic corrosion, the closer the test comes to the actual situation, the more accurate will be the results. The environment must be accurately modeled, with the amount of any constituents that might affect the reactions accurately reproduced and the amount of fluid flow reproduced as well. The materials tested should accurately reflect the materials of interest in composition, thermal processing, and surface films or treatments. If materials are to be tested as a couple, the geometry should reflect as closely as possible that being studied. Finally, galvanic corrosion, like any other form of corrosion, can be strongly time-dependent. Tests must be conducted over sufficient duration to ensure that the results can accurately predict corrosion behavior over the service life anticipated.

#### 2.07.8.2 Testing Hardware

The most accurate test is one in which the actual hardware is exposed in the actual environment for the anticipated service life. In practice this seldom can be done, so that approximations may be required. The considerations for hardware testing are discussed elsewhere.<sup>35</sup>

#### 2.07.8.3 Making a Galvanic Series

If a galvanic series is to be constructed, it is important that the materials and environment accurately reflect those of interest. In many environments, corrosion

**Figure 25** Principle of operation of counter-current device. Reproduced from Shifler, D. A. Advanced measures to control galvanic corrosion in piping systems, CARDIVNSWC-TR-61-99-18 Naval Surface Warfare Center Carderock Division, Bethesda, MD, September 1999.

potential varies with time, so that the length of time of the measurement must be long enough to allow measurement of the full range of potentials. These, and other considerations for developing a galvanic series, are discussed in more detail elsewhere.<sup>5</sup>

#### 2.07.8.4 Determining Polarization

Polarization curves may be developed in a variety of ways, depending on the corrosion system being modeled. Potentiodynamic polarization curves are generated by holding a specimen at a given potential and gradually sweeping the potential in one direction while measuring the current required. If the starting potential is the corrosion potential, then an anodic polarization curve is generated by sweeping in the positive direction, while a cathodic polarization curve is generated by sweeping in the negative direction. Sometimes scans are started at a cathodic potential and swept in the positive direction, generating both anodic and cathodic branches of the polarization curve in a single scan. Sometimes the specimens may be pre-exposed before starting the scan either freely corroding or at a potential indicative of the likely coupled potential. The speed of the potential scan is important, with slower usually giving better results. Details of generating polarization curves are discussed elsewhere.<sup>4,37,40-44</sup>

Polarization curves can also be generated potentiostatically by taking a series of specimens and

holding each at a different constant potential while measuring current as a function of time. This better approximates the potential behavior of a galvanic couple than a potentiodynamic scan, and current stability over time is easily obtained, but the technique is very labor and time intensive and is seldom used in practice. Details of how to perform this type of testing are discussed elsewhere.<sup>4,42,45,46</sup>

Actual galvanic couples of the materials of interest may be exposed in the proper environment while the coupled potential and galvanic current are measured as a function of time. Although the exact geometry is usually not modeled in this type of test, typically the anode-to-cathode area ratio is modeled by adjusting specimen size. This type of testing yields galvanic current information which may not be directly related to the magnitude of galvanic corrosion, but if the anode and cathode corrosion potentials are more than 120 mV apart, the anodic reactions on the coupled cathode are almost completely suppressed and the cathodic reactions on the anode are almost completely suppressed, so that the galvanic current will give a rough measure of the anode corrosion rate.<sup>4</sup> Exposure testing of coupled specimens is discussed elsewhere.<sup>4,35</sup>

#### 2.07.8.5 Determining *IR* Drop

The above testing usually does not take into account *IR* drop. *IR* drop can be measured during an exposure of galvanic couples either by using a small

reference electrode or Luggin–Haber capillary and moving it near the various surfaces, or by rapid interruption of the galvanic current if this current travels through an external wire followed by immediate measurement of potential. Typical interruption times are on the order of milliseconds. The various methods of measuring  $IR$  drop are described elsewhere.<sup>47</sup>

### 2.07.8.6 Determining Corrosion Rate

Once corrosion current is known, corrosion rate can be calculated using Faraday's law.<sup>48</sup> If the anode and cathode corrosion potentials are more than 120 mV

apart, the current that can be used in Faraday's law calculations is the galvanic current. If not, Evans diagrams must be used to determine reaction currents that can be put into Faraday's law to get corrosion rates of the anode and cathode materials.

An easier method for obtaining corrosion rates is to determine specimen mass of the anode metal before and after an exposure in a galvanic couple or at a potential indicative of the coupled potential. This corrosion rate should be compared to that of a freely corroding specimen of the anode metal to determine the amount of acceleration due to the presence of the couple.

Some highly localized corrosion phenomena, such as pitting and crevice corrosion, cannot be easily quantified by mass loss measurements. In those cases, other methods besides corrosion rate must be used to determine the amount of acceleration of the corrosion by the galvanic couple.<sup>49</sup>

**Figure 28** ISO atmospheric corrosion test using plate material. Reproduced from Hack, H. P. *Corrosion Testing Made Easy*; NACE International: Houston, TX, 1993; Volume 2.

### 2.07.8.7 Accelerated Tests

Accelerated testing to predict galvanic corrosion is not normally productive. Any attempt at accelerating the corrosion has a significant chance of changing the corrosion mechanism, invalidating the data that is collected. It is far more productive to allow the galvanic corrosion to proceed at its normal pace and use accurate current and mass loss measuring techniques to get data in a shorter time period.

### 2.07.8.8 Atmospheric Testing

There are several standard tests for galvanic corrosion in the atmosphere. The most popular of these is called the wire-on-bolt, or CLIMAT, test<sup>50,51</sup> (Figure 26). This test consists of wrapping a wire

made from the anode material around a threaded rod made from the cathode material. If the anode and cathode are not known beforehand, two tests are run with the materials reversed. A control is usually run consisting of the anode wire wrapped around a nonconductive rod so that the non-galvanically accelerated corrosion of the anode material can be compared with its corrosion in the galvanic couple. This test is fast, typically taking 30 days, and sensitive, and only has the disadvantage that the materials must be available in the appropriate wire or threaded rod forms.

For materials that cannot be made into the right form for the wire-on-bolt test, another test using stacked washers of the anode and cathode material alternating can be used.<sup>52</sup> Although this test is not as sensitive and usually requires longer exposures, it is

<sup>b</sup>The + sign indicates that iron has a more negative standard electrode potential than the second metal.

not necessary to know before hand which material is the anode. Although it has many advantages, this test is no longer covered by a current standard in ASTM. The test specimen is shown in [Figure 27](#).

Sometimes deterioration in properties such as tensile strength or modulus due to galvanic corrosion is needed. For this, a plate test was designed and standardized by ISO.<sup>53</sup> In this test, a plate of the anode material has a strip of the cathode material affixed to it. After exposure, the anode plate can be cut into tensile specimens to test for deterioration of physical properties. Like the wire-on-bolt test, if the anode is not known beforehand, two tests are run with the materials reversed. Like the washer test, longer exposures are required but the plate form of the material is usually easier to get ([Figure 28](#)).

When performing atmospheric testing there are variables that must be considered. The amount of galvanic corrosion will be a function of the atmosphere, its rainfall acidity, chloride content, and time of wetness, which is a function of rainfall, amount of sunshine, prevailing winds, and other variables. Corrosion can be affected by the angle of exposure of specimens, sheltering from wind and sunlight, and height above ground, among others. Corrosion in the atmosphere is also a function of season; so long tests, or multiple short tests over at least a year, are required to get a proper indication of corrosion performance.<sup>54</sup>

## 2.07.9 Standards

There are many standards used in evaluating and preventing galvanic corrosion. A good reference for these is published by ASTM International,<sup>38</sup> and only a summary is given here. Standards fall into a variety of categories: those that relate to corrosion testing in general such as standards on how to clean specimens after test, general galvanic corrosion test guidelines, specific galvanic corrosion tests such as the CLIMAT test, electrochemical test standards whose results can be used in galvanic corrosion studies such as potentiodynamic polarization tests, and standards for protection methods which can be applied to galvanic corrosion such as cathodic protection standards. These standards have been developed by ASTM International, NACE International, the ISO, the European standards agency (CEN), and numerous countries' standards organizations. Listing of these standards and what they can be used for is beyond the scope of this chapter, and the reader is directed to ASTM International.<sup>38</sup>

## 2.07.10 Useful Galvanic Corrosion Data

The following data may prove useful for estimating rates of galvanic corrosion.

### 2.07.10.1 Atmospheric Corrosion

[Figure 29](#) contains useful data showing galvanic corrosion performance of fasteners in the atmosphere. [Figure 30](#) shows galvanic corrosion performance of a large number of material combinations in urban, rural, and marine atmospheres.

**Table 2** Degree of corrosion at bimetallic contacts<sup>a 59</sup>

Metal considered	Contact metal						
	1	2	3	4	5	6	7
	Gold, platinum, rhodium, silver	Monel, Inconel, nickel-molybdenum alloys	Cupronickels silver solder, aluminum bronzes, tin bronzes, gunmetals	Copper brasses, 'nickel silvers'	Nickel	Lead, tin and soft solders	Steel and cast Iron
1. Gold, platinum, rhodium, silver	–	A	A	A	A	A	A
2. Monel, Inconel, nickel-molybdenum alloys	B	–	A	A	A	A	A
3. Cupronickels, silver solder, aluminum bronzes, tin bronzes, gun metals	C(k)	B or C	–	A	A	A	A
4. Copper, brasses, 'nickel silvers'	C(k)	B or C	B or C(g)	–	B or C	B or C (p)	A
5. Nickel	C	B	A	A	–	A	A
6. Lead, tin and soft solders	C	B or C(t)	B or C(q)	B or C(q)	B	–	A or C(r)
7. Steel and cast Iron (a) (f) (w)	C	C	C	C	C(k)	C(k)	–
8. Cadmium (u)	C	C	C	C	C	B	C

10. Magnesium and magnesium alloys (chromated) (b) (a)	D	D	D	D	D	C	D
11. Austenitic Fe-18Cr-8Ni	A	A	A	A	A	A	A
12. Stainless steel Fe-18Cr-2Ni	C	A or C(s)	A or C(s)	A or C(s)	A	A	
13. 13% Cr	C	C	C	C	B or C	A	A
14. Chromium	A	A	A	A	A	A	A
15. Titanium	A	A	A	A	A	A	A
16. Aluminum and aluminum alloys (n) (a) (w)	D	C	D(e)	D(e)	C(k)	B or C	B or C

<sup>a</sup>Based on data provided by members of the I.S.M.R.C. Corrosion and Electrodeposition Committee and others, and arranged by Mrs. V. E. Rance.

A. The corrosion of the 'metal considered' is not increased by the 'contact metal.'

B. The corrosion of the 'metal considered' may be slightly increased by the 'contact metal.'

C. The corrosion of the 'metal considered' may be markedly increased by the 'contact metal.' (Acceleration is likely to occur only when the metal becomes wet by moisture containing an electrolyte, e.g., salt, acid, combination products. In ships, acceleration may be expected to occur under in-board conditions, since salinity and condensation are frequently present. Under less severe conditions the acceleration may be slight or negligible.)

D. When moisture is present, this combination is inadvisable, even in mild conditions, without adequate protective measures.

### 2.07.10.2 Seawater Immersion

**Figure 31** contains data showing galvanic corrosion performance of fasteners underwater. **Figure 32** shows galvanic corrosion performance of a number of alloys used for valve trim in seawater. **Figure 33**

shows how small variations in composition of seawater caused by pollution can actually reverse the relative galvanic corrosion performance of certain alloys, reversing the anode and the cathode in a galvanic couple.

**Table 3** Degree of corrosion at bimetallic contacts<sup>63</sup> (Continued)

**Table 4** Total corrosion rate acceleration factors due to dissimilar metal coupling at 1:1 area ratio in flowing seawater (mean flow rate about 1–2 m s<sup>-1</sup>)<sup>59</sup>

Coupled metal (wrought form)	Uncoupled corrosion rate <sup>a</sup>	Acceleration factor <sup>b</sup> due to dissimilar metal coupling with:	
		Titanium	Mild steel
Zinc	0.05	4	10
SIC aluminum	0.008	30	60
Mild steel.	0.15	2	1
Lead	0.01	3	3 MS
2% aluminum brass	0.01	3	3 MS
10% aluminum bronze	0.02	3	3 MS
Nickel aluminum bronze	0.015	1	3 MS
Copper	0.03	6	3 MS
90/10 cupro-nickel (1% Fe)	0.02	3	3 MS
Monel 400	0.005	2	3 MS
Stainless steel type 316	0.005	2	3 MS

<sup>a</sup>Corrosion rates relate to general corrosion only and are average rates obtained over about one year's exposure.<sup>b</sup>Acceleration factors quoted for coupled metal corroding unless indicated by suffix (MS) for mild steel corroding.

Quantitative data is presented in, [Table 1–9](#), [Table 1](#) shows weight loss data for iron in saltwater when coupled to various alloys. [Table 2](#) is an extensive list showing how various alloys perform when

galvanically coupled to each other in various environments. [Table 3](#) is a continuation of [Table 2](#) with more alloy combinations. [Table 4](#) gives the amount of galvanic corrosion of various alloys when they are

coupled to titanium or mild steel. **Table 5–7** can help to predict galvanic corrosion performance in seawater heat exchangers. **Table 5** shows galvanically accelerated crevice corrosion when Monel K-500 is

**Table 5** Maximum depth of crevice attack for couples of alloy K-500 and super duplex stainless steel<sup>60</sup>

Couple	Alloy	Maximum pit depth (mm)	
		Washer/plate	Plate/plate
1	K-500	0.26	0.33
	K-500	0.12	0.30
2	Super duplex	0.00	0.00
	Super duplex	0.00	0.00
3	Super duplex	0.00	0.00
	K-500	0.32	0.35
4	Super duplex	0.00	0.00
	K-500	0.42	0.44
5	Super duplex	0.00	0.00
	K-500	0.52	0.50

Couples were at a 1:1 area ratio and exposed to natural sea-water at ambient temperature for 84 days.

**Table 6** Corrosion rate of Muntz metal coupled to various condenser tube alloys<sup>60</sup>

Tube alloy	Corrosion rate (mm year <sup>-1</sup> )	
	Inlet end	Outlet end
None	0.225	0.225
90/10 Cu-Ni	0.846	0.279
6% Mo austenitic	2.80	2.31
Titanium	6.96	6.99

This information is taken from Fu and Chow.<sup>16</sup>

coupled to a super duplex stainless steel. **Table 6** presents galvanic corrosion information for Muntz metal when coupled to other seawater heat exchanger alloys. **Table 7** shows the amount of galvanic corrosion that can occur in heat exchangers when aluminum bronze tubesheets are coupled to stainless steel or titanium tubes. Other useful data for predicting galvanic corrosion of Naval seawater valve materials can be found in Hack.<sup>56</sup> **Table 8** is useful for comparing galvanic corrosion performance of a variety of different alloys used in seawater when galvanically coupled to each other. Finally, **Table 9** shows the effect of galvanically coupling a large variety of different materials to a titanium alloy at various area ratios and flow rates in seawater.

Data given in Hack<sup>57</sup> contain extensive polarization data in seawater at various flow rates that can be used for predicting galvanic corrosion between some common materials used in seawater at any area ratio. This information is also useful as boundary conditions for computerized boundary element analysis for prediction of the amount and spatial distribution of galvanic corrosion and cathodic protection.

### 2.07.10.3 Other Environments

Finding existing galvanic corrosion data in environments other than the atmosphere or seawater can be challenging, and frequently such data do not exist and must be created by running tests. **Figures 34 and 35** show galvanic series generated in carbon dioxide or hydrogen sulfide environments. Scattered data are also contained in some of the general corrosion texts or guides.<sup>59,63–66</sup>

**Table 7** Effect of temperature on the galvanic corrosion of aluminum bronze (alloy D) coupled to 6% Mo austenitic stainless steel or titanium heat exchanger tubes<sup>60</sup>

Alloy	Tube end	Corrosion rate (mm year <sup>-1</sup> )			
		Seawater at 22 °C	Brackish water at 22 °C	Seawater at 6 °C	Brackish water at 11 °C
6% Mo austenitic	Inlet	0.633	0.117	0.048	0.097
	Outlet	0.634	0.150	0.087	0.224
Titanium	Inlet	1.86	0.201	0.059	0.201
	Outlet	3.03	0.373	0.049	0.226

This information is taken from Ref. 16.

**Table 8** Galvanic corrosion in seawater at 1:1 area ratio

Alloy Inducing galvanic effect	Seawater Velocity, ft/s	Corrosion rate (mpy) measured on sample of

### 2.08.1 Introduction

Environment-assisted cracking (EAC) is the gradual growth of cracks under the combined – usually simultaneous – influence of stress and environment. The stress may be applied or internal (residual). The environment may be an aqueous solution or moist atmosphere, a nonaqueous liquid such as ammonia, a gas, a liquid metal, or a solid metal at a high homologous temperature. Whenever the environment is an electrolyte, the EAC process must have a partly electrochemical (i.e., corrosion) character. This may be the dominant factor or a secondary one, depending on the details of the particular system. A simple electrochemical effect is the discharge of hydrogen ions during corrosion of steel in water; the resulting hydrogen atoms may diffuse into the steel and cause embrittlement.

When the stress is more or less static, or varies over a small range, EAC is called as stress corrosion cracking (SCC), hydrogen embrittlement (HE), or liquid metal embrittlement (LME). When a blatantly cyclic stress is present, EAC is usually called corrosion fatigue (CF), hydrogen-assisted fatigue, and so on, although some specialists argue that within this category there are separate phenomena called ‘true corrosion fatigue’ and ‘stress corrosion fatigue’ (discussed later). **Figure 1**, from Andresen, shows the extremes that are easily categorized as ‘static’ or ‘fatigue’ loading, and some of the possibilities in between.

Even if we are sure that a cracking phenomenon is caused by hydrogen (as in the SCC of high-strength steels), we still call it SCC if it occurs under natural

**Figure 1** Illustration of the loading patterns that may occur in a component at risk of EAC, and the appropriate nomenclature. Courtesy of P.L. Andresen.

corrosion conditions. Where the distinction becomes blurred is when the steel is coated with a mildly sacrificial metal such as cadmium, and hydrogen may be absorbed through this galvanic action and not by corrosion of the steel substrate. Under full-scale cathodic protection, we would not refer to SCC, but to HE.

In principle, any EAC problem can be mitigated in one of three ways – modify the stress, modify the material, or modify the environment (which would include changing the electrode potential, either by galvanic contact or by imposing a potential). Thus, EAC presents a large number of possible variables, but also a large number of possible countermeasures. A major variable is yield strength – strong alloys are generally more susceptible to EAC, especially where hydrogen absorption is involved, and this limits their application in practice.

Many international conferences on EAC have been held since the 1940s, but a particular landmark was the Ohio State University conference in 1967.<sup>1</sup> This dealt mainly with SCC, but specialist proceedings are also available on CF<sup>2</sup> and LME,<sup>3</sup> recently called ‘metal-induced fracture’ in view of cracking observed with solid metal contact. A regular conference series on hydrogen effects in materials is held in Jackson Hole, Wyoming and has recently joined with a series pioneered in France called ‘Corrosion–Deformation Interactions.’<sup>4</sup> The most recent conference that attempted to cover the entire field of EAC was held in Banff, Canada, in 2004,<sup>5</sup> and was a sequel to a 1987 conference that had a similar ambitious scope.<sup>6</sup> There is a vast journal literature on EAC.

The crack growth rates (CGRs) in EAC vary quite widely, and the lower limit of CGR, if there is one, has probably not been observed yet. At some point, especially at elevated temperatures, the CGR will become equal to a creep crack growth rate, at which point it may not be appropriate to talk about EAC. Creep, though, can also be affected by the environment. There is a whole area of research called creep–fatigue–oxidation interaction, and a related phenomenon that occurs under static loading, called oxygen embrittlement.<sup>7</sup> These phenomena are usually studied in the context of gas turbine materials, but there may be a link with SCC in hot water or steam systems.

For SCC, the CGRs tend to range from about  $10^{-12} \text{ m s}^{-1}$  ( $30 \mu\text{m year}^{-1}$ ) to  $10^{-7} \text{ m s}^{-1}$  ( $9 \text{ mm day}^{-1}$ ). In the laboratory, faster rates are possible. From an industrial perspective, the lower range of rates is manageable by appropriate inspection; the highest rates are not, but they occur in certain well-known high-risk situations, such as contact of austenitic stainless steel with strong, hot chloride solutions, or contact of a susceptible alloy with mercury. Usually something has gone badly wrong when such rates occur. The fastest form of EAC is LME, which can appear almost instantaneously in certain combinations such as mercury (or liquid gallium) and a high-strength aluminum alloy.

## 2.08.2 Appearance of EAC

There are three common types of crack morphology in EAC: intergranular, transgranular (cleavage-like), and transgranular (fatigue-like) (Figure 2). When a CF surface shows ‘brittle striations,’ there is not much distinction from a cleavage-like SCC fracture surface, which might be obtained in the same environment by monotonic dynamic straining. There are also some cases of HE (in lower strength steels and some aluminum alloys) in which the fracture surface is dimpled, but the dimples are smaller than those that occur in a normal ductile fracture performed in air.

Classical cases of SCC (brass in aqueous ammonia; carbon steel in hot caustic or nitrate solution) were usually intergranular, but later the transgranular form became more common as new materials and technologies were developed, chiefly process industries that exposed austenitic stainless steels to the risk of SCC due to hot aqueous chloride. CF is usually transgranular, but can be intergranular at low cyclic stress (intensity) amplitudes, or in alloys with sensitive grain boundaries, such as sensitized stainless steel or

high-strength aluminum alloys. LME is usually intergranular in practice, but occurs in monocrystals of many metals (Al, Ni, etc.) in the laboratory. Hydrogen affects both intergranular and transgranular fracture. A recent review by Lynch discusses many fractographic details seen in EAC, and proposes that

(a)

(b)

(c)

**Figure 2** Fracture appearance in EAC: (a) Mainly intergranular SCC of Alloy 600, courtesy Bob Cottis, School of Materials, University of Manchester; (b) Transgranular cleavage-like SCC of Alloy 800 in 50% NaOH at 280 °C; (c) Fatigue of a nickel monocrystal showing successive regions of fracture in mercury (brittle striations), hydrogen (brittle striations), and argon (ductile striations). Reproduced from Lynch, S. P. *Acta Metall.* **1988**, 36, 2639–2661.

many EAC phenomena might be unified under an adsorption-induced plastic microfracture type of mechanism.<sup>8</sup>

The phenomenon of hydrogen-induced cracking of steel (HIC) occurs in pipes carrying sour oil or gas. It is not driven by preexisting external or internal stress, but by the pressure of hydrogen that is discharged as part of a corrosion reaction, enters the metal at a huge effective activity in accordance with the Nernst equation, then recombines to form high-pressure gas at defects inside the metal. It is only barely to be considered a case of EAC, and is not discussed further in this article. Importantly, though, when we increase the strength of steel used to make such pipes, we risk a transition from HIC to SSCC (sulfide stress corrosion cracking) which is a true SCC phenomenon, also caused by hydrogen, but under the influence of the stress in the pipe (**Figure 3**).

One difference that usually helps to distinguish SCC and CF is the multiplicity of cracks. CF, like ordinary fatigue, usually shows few and relatively flat cracks, whereas SCC often shows complex branched and intertwined cracks (**Figure 4**). An important factor in creating such crack patterns is the amount of local driving force (loosely, the local stress intensity factor  $K$ ) that is needed to propagate the crack. If this is low, then the presence of many parallel or overlapping cracks (which reduces the  $K$  value at each crack tip) is not a hindrance to the propagation of each one.

Cracking of welded or cast components cannot always be classified as ‘intergranular’ or ‘transgranular,’ and the morphologies are often complex.

### 2.08.3 Stress and Strain in EAC

Strong alloys are used because they need to resist stresses in service, so for these materials the main source of stress is often an externally applied load, such as

**Figure 3** Distinction between HIC (hydrogen-induced cracking) and SSCC (sulfide stress corrosion cracking) as made in the oil and gas industry. HIC is not caused by the stresses present in the pipe or vessel, but by the pressure of internal hydrogen gas.

**Figure 4** Illustration of the meandering path taken by typical stress corrosion cracks, indicative of a low local driving force required for crack advance (transgranular SCC of AISI type 316 stainless steel in 4 M NaOH at 280 °C).

internal pressure in a pipe. Ductile alloys such as austenitic stainless steel are not much used for major load-bearing structure, so they usually crack under the influence of internal residual stresses (e.g., at welds). Cyclic stresses, if present, can arise from rotation, vibration, thermal fluctuation, intermittent operation, and so on. Superimposition of static and cyclic stresses is a major topic in fatigue, and thus also in corrosion fatigue.

A distinction between EAC and ordinary fatigue is that hardening is generally detrimental for EAC, whereas it is one of the ways to improve fatigue resistance.

Low-frequency, low-amplitude cycling can cause major enhancement of SCC under conditions where it would not be appropriate to refer to fatigue – such as one cycle per startup of a nuclear reactor, or one cycle per spring thaw for a pipeline crossing a riverbed. This reflects a general truth about SCC, which is that for the most part it is a plastic-strain-driven phenomenon (at least that is the prevailing opinion – this may change). If the load is completely static, cracking is less likely because any transient creep strain becomes exhausted, and there is nothing to drive processes such as oxide film rupture. R.N. Parkins is credited for much of the modern understanding of this issue, and for the idea that there exists a continuum of EAC from SCC through intermediate cases to true CF.<sup>9</sup> Figure 5 illustrates, schematically, the effect of low-amplitude cycling on the two kinds of external pipeline cracking studied by Parkins – ‘near-neutral pH’ and ‘carbonate–bicarbonate.’

**Figure 5** Schematic behavior of carbon steel pipeline material subject to external SCC with and without low-amplitude cyclic loading. In high-pH carbonate–bicarbonate, the time to failure decreases from line A to line B upon cycling. In near-neutral pH bicarbonate–CO<sub>2</sub>, there is scarcely any cracking without cycling (line C) but cracking occurs with cycling (line D).

EAC of pressurized or otherwise actively loaded equipment made of high-strength materials causes particular concern because it can lead to catastrophic failure. A crack initiates, grows at an increasing rate, then fast fracture occurs when  $K$  (or  $K_{\max}$  in the case of CF) reaches  $K_c$ . On the other hand, in something like a stainless steel pipe carrying a corrodent under low pressure, where there is no meaningful  $K_c$ , the outcome of EAC is usually a leak. This can be serious, but it is usually more manageable than a fast rupture. Naturally, there are cases that fall somewhere in between, and here there may be uncertainty as to the structural outcome of an EAC incident; modeling and simulation can provide some of the answers, but some kind of full-scale component test may be required.

When fracture mechanics methods are applied to SCC, HE, or LME, a flat or ‘plateau’ region is observed at intermediate  $K$  values – Figure 6. (The author’s Ph.D. advisor, G.T. Burstein, used to insist that such features should be called ‘ledges,’ not ‘plateaux.’) This shows that a limiting condition has been reached where something other than the mechanics controls the crack growth rate. This ‘chemical’ rate control is generally due to a rate-limiting dissolution, diffusion, or adsorption process. Also, the critical stress intensity factor  $K_c$  may be reduced, in effect, by hydrogen-producing environments; the implications of this are both serious and poorly understood. (‘In effect,’ because  $K$  is a static quantity and the reduction in apparent  $K_c$  value may be due to dynamics associated with the overload of the crack – that is,

**Figure 6** Schematic crack velocity versus stress intensity curve for EAC (without cyclic loading) showing the ‘plateau’ region at intermediate  $K$  values. Such curves are often drawn as though there is no reduction in  $K_c$  due to the environment, but in reality such reductions (dashed line) can occur and are troublesome in certain safety-related prediction procedures.

there is a strain rate sensitivity of the apparent reduction in  $K_c$ .)

Stress in a real component is always multiaxial to some extent, but most SCC behavior is referred to the principal tensile stress, whether residual or applied. The stress *state* is important, though, in hydrogen-affected EAC. This is because three-dimensional (3D) lattice dilation can increase the solubility of hydrogen in the metal and thus, potentially, the susceptibility to cracking. A number of authors have shown easier cracking in mode I (tension) loading than in mode III (torsion) in certain systems believed to involve hydrogen entry into the metal.<sup>10</sup>

In components subject to fatigue, the mean stress is rarely zero. Certain effects of the  $R$  parameter (minimum load/maximum load) are known in ordinary fatigue, but in CF these are magnified. To some extent, this can be dismissed as the superimposition of SCC (due to the mean load) on CF (due to the cyclic load), but as CF occurs in environments where SCC does not, it is an important consideration. **Figure 7** indicates the distinction between ‘true corrosion fatigue’ and ‘stress corrosion fatigue’ that is made by some authors. The hump or plateau feature at intermediate  $\Delta K$  values is due to SCC-like crack growth, and thus becomes more noticeable with increasing mean stress. Cyclic loading frequency is a key variable affecting crack growth in CF, in contrast to ordinary fatigue, because the corrosion process (this also applies to hydrogen-assisted fatigue) needs time to do its work on each cycle, and if the frequency is too high, the cracking behavior may revert to that seen in an inert environment. It is easy to see that all this is amenable to a mathematical modeling approach based on superposition of a time-dependent

**Figure 7** Fatigue crack growth curves showing some different possible effects of an environment. Line A is for an inert environment. Then, the distinction is made between ‘true corrosion fatigue’ (line B) and ‘stress corrosion fatigue’ (line C; alternatively the dashed line), which shows a plateau-like feature at intermediate  $\Delta K$  values. Most corrosion engineers do not make this distinction, and most corrosion fatigue is of type C.

‘monotonic’ or ‘SCC’-like element of crack advance and a ‘cyclic’ contribution.

One type of SCC has its own special name. SICC (strain-induced corrosion cracking)<sup>11</sup> occurs in steel exposed to hot water when sufficiently large strains arise to fracture the magnetite film on the surface. This is not much different from any other case of SCC where dynamic strain is mandatory, and, indeed, CF occurs quite readily under such conditions, at least in the laboratory.

## 2.08.4 Test Methods for EAC

An excellent manual on SCC testing is available, written by Sedriks.<sup>12</sup> Testing for CF is no different from ordinary fatigue testing, except that the environment has to be contained around the sample – this of course presents a challenge when the environment is a gas or a hot, pressurized aqueous solution. Electrochemistry adds another level of complexity, especially in an autoclave.

Regarding specimen design, all EAC testing can be classified as (a) smooth-specimen testing, or (b) defected (e.g., precracked) specimen testing, and for SCC these can be further subdivided into selfloaded (e.g., bolt-loaded) and machine-loaded designs (fatigue, unless purely thermal, generally requires a testing machine). The advantage of using a machine, despite the extra complexity, is that the loading can be active; this is especially important in view of the proven role of low-level dynamic strains in SCC. Also, one can use a

test machine to do a slow strain rate test – an important accelerated method for mapping out SCC susceptibility rapidly and economically.

For SCC, HE, LME, etc. one can use precracked specimen testing to obtain the CGR, or crack velocity ( $v$ , or  $da/dt$ ) as a function of the stress intensity factor  $K$  as shown in **Figure 6** – although only up to a point for ductile alloys, which undergo large-scale yielding that puts a limit on  $K$  values that can be validly quoted. This does not affect the study of crack growth at relatively low  $K$  values near the threshold ( $K_{th}$  or  $K_{ISCC}$ ) below which crack growth stops altogether (it should be noted that not all authors agree with the existence of a true  $K_{th}$  for SCC). In some types of SCC, copious multibranched cracking makes  $K$  a questionable parameter, but this can be handled to some extent by machining side grooves on the specimen to keep the crack straight. The determination of  $da/dt$  is a big subject in itself – the most sophisticated laboratories generally use sensitive and stable electrical resistance (DC potential drop) methods.

Similarly, we can use precracked specimens to obtain  $da/dN$  versus  $\Delta K$  curves in an environment. This is one of the most difficult of all corrosion experiments, especially if done in an autoclave.

For the most difficult types of EAC – such as the SCC of annealed stainless steels in reducing high temperature water, or the SCC of pipeline steels in near-neutral pH solutions, or HE of ordinary carbon steels in general, the occurrence of truly stable crack growth at constant  $K$  is questionable. In that case, some dynamic loading, such as fatigue loading or periodic unloading, is mandatory for stable cracking to occur. Clearly, this might represent a nomenclature problem – but generally we prefer to stay with ‘SCC’ (see **Figure 1**) so long as the mean stress dominates the cracking behavior. Slow strain rate testing especially exaggerates the propensity of such systems to show SCC in practice. If we believe the results of slow strain rate tests, we would never cathodically protect steel.

Data presentation is straightforward for precracked specimen testing:  $da/dt$  (crack velocity) versus  $K$ , or  $da/dN$  versus  $\Delta K$ . For smooth-specimen testing, there is a multitude of types of data that can be gleaned from a test – for fatigue, the presentation is generally in the form of  $\Delta\sigma$  (cyclic stress range) versus  $N_f$  (number of cycles to failure), and the effect of an environment is often to remove the ‘fatigue limit’ at low  $\Delta\sigma$  – **Figure 8** (incidentally, such testing is normally done at quite a high frequency, so crack growth may not be much affected by corrosion – the main effect is to assist crack initiation). For SCC,

**Figure 8** Disappearance of the fatigue limit in corrosion fatigue tests conducted on smooth specimens.

smooth self-loaded samples can be examined for cracks after a fixed period of time, or examined periodically and reimmersed each time (this seems dubious, but has been done, especially for long tests in hot, pressurized water), or monitored continuously by optical microscopy or acoustic emission. Multiple samples may be tested at the same condition. Ideally, the output should be a plot of time to failure against stress. Machine-loaded samples, and especially slow strain rate tests, enable a better distinction of crack initiation and crack growth – for slow strain rate, one can obtain a variety of quantities as discussed by Sedriks – strain to failure (normalized to air), reduction in area at fracture, maximum stress, and so on. Low-amplitude cyclic strains (not enough to be called fatigue) often enhance SCC susceptibility, as discussed earlier, and can be applied automatically with some modern slow strain rate machines.

### 2.08.5 Mechanisms of the Environmental Enhancement in EAC

A detailed discussion of crack-tip mechanisms is deferred to the SCC chapter. Broadly, the proposed mechanisms fall into several categories, which still excite controversy.

- Decohesion or enhanced plastic rupture caused by hydrogen or liquid metal adsorption or absorption.
- Slip-dissolution or slip-oxidation – that is, crack growth by a highly localized corrosion process, exacerbated by local plastic deformation.
- Film-induced substrate fracture (film-induced cleavage).
- Creep-like mechanisms, for example, ‘surface mobility,’ vacancy injection.

Many reviews are available – including the one by the author.<sup>13</sup>

In CF the possibilities are expanded, and simple anodic dissolution (without any apparent surface film) or simple passive film formation can cause an enhancement in crack initiation and  $da/dN$ . Generally CF can be seen with more subtle environmental effects than SCC.

Not much discussion has occurred lately on mechanisms of LME, but there was an intriguing study showing that in one well-known system (Ga on Al) first-principles quantum calculations could show that surface alloying (intermixing of Ga and Al in the first atomic layer) should occur.<sup>14</sup> This might be a general mechanism of, or rather first step in, LME. In any event, whatever the interaction is, it is extremely shallow, yet causes the fastest of all EAC phenomena. Quantum calculations are also giving insight into hydrogen effects in metals.

#### 2.08.5.1 Occurrence of EAC in Pure Metals

CF and LME are well known to occur in pure metals, but SCC of pure metals was controversial until recently. Extremely pure iron does not crack in nitrate or caustic (and presumably other intergranular cracking environments), and intergranular SCC of pure copper could be dismissed as some kind of grain-boundary segregation effect, but in fact it should have been obvious from the earliest observations of transgranular SCC in carbon steel that pure iron would also crack transgranularly in the same (peculiar) environments – CO–CO<sub>2</sub>–H<sub>2</sub>O, and anhydrous liquid ammonia. The issue was laid to rest by the observation of transgranular SCC in pure copper, which has occurred now and again in practice. This is discussed further in the Chapter 2.09, Stress Corrosion Cracking.

#### 2.08.6 Emerging Environments and Future Outlook

Until the advent of the slow strain rate test in the 1970s, most EAC phenomena were discovered in the field, not in the lab. Even now we can be caught out by a new environmental effect. So, as technologies develop, we need to anticipate possible EAC problems. For example, the prospects for supercritical water-cooled nuclear power plants are critically dependent on the development of new materials that are resistant to EAC in such extreme environments

(and with neutron irradiation, radiolysis, etc.). Other new energy technologies such as thermochemical–electrochemical hydrogen production have unusual environments that could cause unexpected EAC problems. Finally, even the ‘pure water’ problem is not solved yet, because next-generation nuclear plants will have to operate for 60–100 years, and late-onset EAC is possible in the presently used materials.

We need to develop multiscale understanding of EAC, from the quantum level to the component level, before we can truly have a predictive capability. We know already that EAC can be *controlled* at all these scales – one can add some element that interacts chemically with hydrogen and mitigates its embrittlement effect, or one can induce a surface residual stress in a whole component that prevents crack initiation. In between, one can control intergranular EAC at the granular level, by inducing the formation of a high fraction of geometrically special, nonsusceptible grain boundaries – so-called grain boundary engineering. So, despite the formidable challenges presented by EAC, we have a wide range of countermeasures at many length scales.

## 2.10.1 Introduction

There are many applications in which the yield strength of the material of construction is a limiting factor in the design. For example, a large proportion of the weight of an offshore oil production platform consists of the structure required to resist wave forces, with a relatively small proportion being the 'topside' equipment that actually does the work. If the strength of the material of the structure could be increased, this would allow the structure itself to be made lighter, with the consequence that the weight of the topside equipment could be increased. Thus, materials offering high strength-to-weight or strength-to-volume ratio are in high demand in many fields of engineering. Steels can be produced with yield strengths above 2000 MPa, and at first sight, one might expect these to have widespread application. Unfortunately, things are not that simple, and as the yield strength of materials is increased, other mechanical properties tend to decrease. In particular, the materials become more susceptible to brittle fracture, especially when assisted by environmental factors, such as hydrogen embrittlement, stress corrosion cracking, or corrosion fatigue. The related problem of hydrogen-induced blister formation or hydrogen-induced cracking tends to be more of a problem in lower-strength steels used for crude oil transmission pipelines.

It is now well established that high-strength steels are susceptible to embrittlement by dissolved hydrogen, and the majority of stress corrosion cracking (SCC) failures of these materials are attributed to hydrogen embrittlement. This should not be taken to imply that other mechanisms of SCC do not occur. However, the ease with which hydrogen can be picked up from aqueous environments is such that other SCC processes are rarely a practical problem for high-strength steels.

This document is based on a Chapter on SCC of High Strength Steels that was produced for the 3rd Edition in about 1989. It has been revised for the 4th Edition to incorporate some updated references, particularly in respect of mechanistic aspects of hydrogen embrittlement, and to provide some information on hydrogen embrittlement of materials other than carbon and low-alloy steels. Hydrogen embrittlement continues to be a major area of research, with nearly 9000 publications in the period from 1980 to Spring 2009. A number of reviews of the aspects of hydrogen embrittlement have been published in the last 25 years<sup>1-3</sup> to which the reader is referred for further information.

## 2.10.2 Terminology

As with several aspects of corrosion technology, the terminology of the effects of hydrogen on metals is somewhat confused. We can identify two general classes of hydrogen effect:

- quasi-brittle fracture of higher strength materials that can occur with relatively low concentrations of hydrogen; we term this hydrogen embrittlement, although some processes that almost certainly occur by this mechanism are also termed SCC, such as the SCC of high-strength aluminum alloys in water or water vapor; and
- surface blistering and internal cracking at sulfide and other inclusions in lower-strength materials (primarily carbon steels) due to very high internal hydrogen fugacities, leading to hydrogen pressure-induced cracking, commonly termed hydrogen-induced cracking (HIC) (it is unfortunate that the term 'hydrogen-induced cracking' has also been used as a generic term for any cracking due to hydrogen); processes in this class are discussed separately in the subsequent **Chapter 2.11, Cracking Stimulated by Hydrogen**.

However, as is often the case in corrosion, things are not really that simple, and there is a spectrum of behaviors between these two extremes, including processes such as stress-oriented hydrogen-induced cracking (SOHIC), sulfide stress cracking (SSC) of pipeline steels, and hydrogen-induced stress cracking (HISC) of duplex stainless steels. Just to complicate the terminology further, there is the phenomenon of hydrogen cracking that is experienced at higher temperatures as a result of internal methane production by reaction between dissolved hydrogen and carbon.

## 2.10.3 Entry of Hydrogen into Metals

Hydrogen can enter metals, either from the gas phase, or by way of the electrochemical reduction of hydrogen-containing species, from the aqueous phase. This section is largely based on work on carbon and low-alloy steels.

### 2.10.3.1 Entry from the Gas Phase

Several models have been proposed for the entry of hydrogen from the gas phase, and the details of the process remain somewhat uncertain. In general terms however, the reactions involved are the adsorption of

molecular hydrogen (other gases such as hydrogen sulfide can also act as a source of hydrogen, but they will typically require water to facilitate the reactions involved and are arguably aqueous phase reactions), the dissociation of the hydrogen molecule to produce hydrogen atoms adsorbed onto the surface, and the subsequent diffusion of the adsorbed hydrogen atoms into the metal lattice:

For perfectly clean and film-free iron surfaces, the rate-controlling step in this process may be the dissociation step.<sup>4</sup> This will be proportional to the partial pressure of hydrogen, and consequently so will the rate of hydrogen entry into the metal. In more realistic situations, surface films such as passive or air-formed oxide films, or the presence of gases, such as oxygen, which adsorb competitively with hydrogen, may play an important role.

### 2.10.3.2 Entry from the Aqueous Phase

The mechanism of electrochemical production of hydrogen on steel in aqueous solution has received much attention. It is accepted that the reaction occurs in two main stages. The first of these is the initial charge transfer step to produce an adsorbed hydrogen atom, known as the Volmer reaction. In acid solution, this involves the reduction of a hydrogen ion.

In neutral and alkaline solution, where the concentration of hydrogen ions is very low, the reaction switches to the reduction of water molecules:

The second stage of the reaction to produce molecular hydrogen may occur through either of two mechanisms. In the first of these, known as chemical desorption, chemical recombination, or the Tafel reaction, two adsorbed hydrogen atoms combine to produce a hydrogen molecule:

Alternatively, the adsorbed hydrogen atom may participate in a second electrochemical reaction, known as electrochemical desorption, or the Heyrovsky reaction:

For iron, it is reasonably well established that the reaction goes by way of chemical recombination under most circumstances, although there is some evidence that electrochemical desorption may take over in very alkaline solutions or at large overpotentials.

A third reaction, which goes in parallel with the desorption reaction, is the entry of atomic hydrogen into the steel from the surface adsorbed state:

In most circumstances, the kinetics of this reaction are controlled by the rate at which the hydrogen can diffuse into the underlying steel, and this reaction is essentially in equilibrium. Consequently, it is difficult to study the kinetics of this reaction. A particular situation in which this may be very important relates to the conditions at crack tips, where the hydrogen may be transported into the bulk by dislocation motion, giving rise to very high rates of hydrogen entry.

As the hydrogen entry reaction is generally in equilibrium, the hydrogen concentration just below the entry surface is directly related to the surface concentration or coverage. Consequently, the rate of entry of hydrogen into the steel is controlled by the balance between the first and second stages of the hydrogen evolution reaction, since these control the coverage of adsorbed hydrogen. In the case of chemical recombination as the second stage in the reaction, the rate of hydrogen evolution is proportional to  $(\text{H}_{\text{ads}})^2$  (since two adsorbed hydrogen atoms are involved in the reaction), while the rate of hydrogen entry (or the equilibrium concentration just below the surface, which is usually the controlling factor) is proportional to  $(\text{H}_{\text{ads}})$ . Thus, as the cathodic current increases so the subsurface hydrogen concentration (and hence, the rate of hydrogen diffusion through a membrane) increases as the square root of the cathodic current (assuming that the current due to hydrogen entering the steel is small compared to that due to hydrogen evolution, as is usually the case).

However, when the second stage in the hydrogen evolution reaction is electrochemical desorption, the rate of this reaction is increased as the potential becomes more negative, and the adsorbed hydrogen concentration may remain constant or fall, according to the detailed electrochemistry. This results in curves such as that shown in **Figure 1** for steel in seawater.

**Figure 1** Hydrogen permeation current as a function of applied potential, showing effect of change in reaction mechanism below  $-1200$  mV (SCE). Reproduced from Obuzor, U. W. PhD Thesis, UMIST, Manchester 1989.

Whether the adsorbed hydrogen is produced from the gas phase or from aqueous solution, it appears that the presence of hydrogen atoms distorts the crystal structure of the metal surface<sup>5</sup> and this results in a surface solubility that is higher than that of the bulk. The depth of this distortion is not clear, but it seems possible that this distorted zone may play an important part in initiating brittle fracture processes.

#### 2.10.4 Location of Hydrogen in Steel

Hydrogen exists in metals in the monatomic form, and is commonly described as atomic hydrogen. In practice, the state of charge of the hydrogen atom is not known with any certainty, but it seems probable that it tends to acquire a slight negative charge by attracting electrons from the valence orbitals of the metal lattice. It has been suggested that this results in a weakening of the metal-metal bond which is responsible for hydrogen embrittlement.<sup>6</sup>

Hydrogen has a very low solubility in the iron lattice, which makes direct observation of the location of the hydrogen atom in the lattice very difficult. The hydrogen definitely occupies an interstitial site in the *bcc* iron lattice. Two such sites are normally associated with interstitial solutes in *bcc* structures, the tetrahedral and the octahedral sites (see Figure 2). Indirect evidence<sup>7</sup> suggests that hydrogen occupies the tetrahedral site.

In addition to interstitial sites in the lattice, hydrogen atoms are also strongly attracted to defect sites in

**Figure 2** Octahedral and tetrahedral sites in the *bcc* lattice.

the metal, and these are referred to as 'traps.' Trap sites include vacancies, solute atoms, dislocations, grain boundaries, voids, and nonmetallic inclusions. Of the various trap types in iron and steel, vacancies are relatively unimportant at ambient temperatures, simply because of their low concentration. Somewhat surprisingly, it appears that grain boundaries in pure iron also trap very little hydrogen, although segregation of carbon and other impurity atoms to the grain boundary can increase the tendency for trapping.<sup>8</sup> The more important trap sites in iron and steel appear to be phase boundaries, dislocations, voids, and inclusions.<sup>9</sup> Trap types may be classified in various ways, two of the more important being related to the number of hydrogen atoms which can be

accommodated in the trap and to the binding energy of the trap. These are summarized in [Table 1](#).

It should be noted that the terms saturable and reversible are rather loosely defined in relation to hydrogen trapping. Thus, some workers take the view that reversible and nonsaturable traps are the same (since the equilibrium hydrogen content of the trap will vary with the fugacity). Similarly, the term reversible is given a slightly different meaning from that in electrochemical reaction kinetics, where it relates to the activation energy of a reaction, rather than the overall free energy change.

There are many ways in which trapping can be studied, but the wide range of trap types and geometries make it difficult to determine the properties of specific trap sites.

Hydrogen trapped in voids consists of adsorbed hydrogen on the walls of the void, together with molecular hydrogen in the void itself. With high fugacities of hydrogen in the steel, such as can be developed in steels in contact with acidic solutions containing hydrogen sulfide, very high pressures may be developed in the void. When combined with the hydrogen embrittlement of the steel around the void, this can lead to the growth of cracks around the void. Such cracks typically develop around nonmetallic inclusions which have been flattened by rolling, giving characteristic blisters lying parallel to the rolling direction. This phenomenon is known as hydrogen-induced cracking.

### 2.10.5 Transport of Hydrogen in Iron and Steel

As a small interstitial atom, hydrogen diffuses rapidly in iron, the diffusion rate being of a similar order to that of solutes in aqueous solution.

**Table 1**     Classification of trap types

<i>Classification</i>	<i>Description</i>
Saturable	The number of sites for hydrogen atoms is fixed (e.g., grain boundaries, dislocations)
Nonsaturable	The number of sites for hydrogen atoms in the trap varies according to the fugacity (e.g., voids)
Reversible	The trap binding energy is relatively small, and hydrogen may escape from the trap as well as enter it
Irreversible	The trap binding energy is large, and hydrogen will not leave the trap at ambient temperature

The study of the transport of hydrogen in steel is commonly undertaken by hydrogen permeation measurements. This involves the permeation of hydrogen through a thin steel membrane (typically less than 1 mm thick). Hydrogen entry may be from the gas phase or from solution, while the flux of hydrogen through the membrane may be determined either by vacuum extraction of the gas to a suitable detector, or, somewhat more simply, by electrochemical oxidation of the hydrogen to hydrogen ions. The latter method forms the basis of the electrochemical hydrogen permeation cell developed originally by Devanathan and Stackurski<sup>10</sup> and illustrated in [Figure 3](#). This has subsequently been developed into a monitoring technique by Berman *et al.*,<sup>11</sup> while Arup<sup>12</sup> has developed a small self-contained sensor using battery technology, shown in [Figure 4](#).

In permeation measurements, the first signs of hydrogen diffusing through 1-mm steel membranes can be observed in a few minutes. The practical measurement of diffusion parameters tends to be rather unreproducible, because of the role of the various forms of trap, which tend to increase the solubility of hydrogen in the steel and thereby decrease the apparent diffusion coefficient. For pure iron at temperatures above  $\sim 350$  K, the activation energy for diffusion is  $\sim 7.6$  kJ mol<sup>-1</sup>, with  $D_0$  being in the region of  $1\text{--}2.5 \times 10^{-7}$  m<sup>2</sup> s<sup>-1</sup>. At ambient temperatures, the activation energy ranges from  $\sim 4$  to 7 kJ mol<sup>-1</sup>, with  $D_0$  ranging from  $\sim 0.5$  to  $1.2 \times 10^{-7}$  m<sup>2</sup> s<sup>-1</sup>. Diffusion coefficients at 298 K are thus  $\sim 7 \times 10^{-9}$  m<sup>2</sup> s<sup>-1</sup>.

The above data relate to very pure iron samples with low dislocation densities. In real steels, the trapping effects result in much lower apparent diffusivities, which are dependent on the metallurgical state of the steel as well as its chemical composition. Typical values for the apparent diffusion coefficient of hydrogen in high strength alloy steel at room temperature are in the region of  $10^{-11}$  m<sup>2</sup> s<sup>-1</sup>.

In the context of hydrogen embrittlement, an important aspect of transport processes is the influence of plastic strain on the behavior of hydrogen in a metal. Brass and Chene<sup>13</sup> reviewed these effects, and concluded:

“The nature of hydrogen-deformation interactions may be complex and opposite effects can be observed during the exposure of iron or nickel base alloys to a hydrogen source:

- (a) Strain may enhance hydrogen ingress in b.c.c. alloys as a consequence of a local destruction of the oxide films, while strain-induced defects favor hydrogen trapping;

**Figure 3** Hydrogen permeation cell (schematic).

**Figure 4** Permeation cell using battery technology. Reproduced from Arup, H. Proceedings of the 9th Scandinavian Corrosion Congress, 1984; p 825.

- (b) Pipe diffusion may occur in the dislocation network of predeformed samples, whereas hydrogen accelerated transport by mobile dislocations is expected during plastic deformation in f.c.c. structures;
- (c) Both the local plasticity and the embrittlement of these alloys are increased by hydrogen."

Using *in situ* observations in an environmental TEM, Robertson<sup>14</sup> has obtained further experimental confirmation of the influence of hydrogen on dislocation dynamics, and confirmed that hydrogen enhanced dislocation mobility.

### 2.10.6 Sources of Hydrogen

The thermodynamics of the reaction of iron with water are such that iron is always thermodynamically capable of displacing hydrogen from water, although the driving force is small at ambient temperatures, except in reasonably strong acids. Thus, iron does not suffer from serious corrosion in oxygen-free neutral

or alkaline solutions. However, rates of hydrogen evolution which are insufficient to cause significant corrosion may still produce enough hydrogen to create a serious embrittlement problem for high strength steels. The hydrogen which is produced dissolves readily in the steel, and remarkably small concentrations of hydrogen (less than 1 ppm) can cause embrittlement. In addition to corrosion itself, many of the standard chemical and electrochemical treatments employed to protect steel against corrosion also tend to drive hydrogen into the steel. Some of the major sources of hydrogen are:

- **Welding** Hydrogen introduced into welds produces a particularly acute problem, as the weld and the heat-affected zone are inevitably regions of high residual stresses, contain inherent defects, and are frequently intrinsically more brittle than the parent material. Thus, it is important to minimize the introduction of hydrogen into welds, even for lower strength steels. Gas welding of steels using an oxyacetylene flame will inevitably introduce hydrogen as a result of the hydrogen-containing gases in the flame. In theory, electric arc welding,

particularly if the arc is protected from atmospheric moisture by inert gas shielding, will not introduce hydrogen. However, with normal manual metal arc welding using flux coated electrodes, it is possible for the flux coating to absorb moisture from the atmosphere, and this will react with the molten steel to produce hydrogen. For this reason, it is good practice to store coated welding electrodes in an oven in order to drive off any moisture.

- *Acid Pickling* This process is widely used for removing rust and mill scale from steel, or for removing internal scales from boilers. The objective of the process is the dissolution of iron oxides or hydroxides, or hardness scales, but at the same time, the iron will also tend to corrode in the acid, with hydrogen evolution as the cathodic reaction. This leads to hydrogen entry into the steel which may lead to hydrogen embrittlement or blister formation due to HIC.

As dissolution of the steel is normally an undesirable side-effect of the pickling process, resulting in loss of metal and wasteful consumption of acid, it is normal practice to add inhibitors (usually referred to as 'pickling restrainers') to the acid. Unfortunately, many of these work by interfering with the hydrogen recombination reaction, rather than the initial production of adsorbed hydrogen atoms. This has the effect of increasing the surface coverage by adsorbed hydrogen atoms, and consequently, the rate of entry of hydrogen into the steel is increased, even though the overall rate of hydrogen production is reduced. For this reason, it is most important that pickling restrainers for use with high strength steels should be tested for their effects on the uptake of hydrogen as well as their efficiency as inhibitors.

- *Degreasing and Cleaning* Various processes can be applied for the removal of grease and other contaminants prior to painting, electroplating, or other surface treatments. Degreasing in organic solvents (e.g., vapor degreasing) is unlikely to generate significant quantities of hydrogen unless the fluid is contaminated with water or other species, such as hydrogen chloride, capable of liberating protons. Cleaning in aqueous alkali without applied polarization is also unlikely to introduce much hydrogen, although any tendency for pitting corrosion due to chloride contamination could give rise to local problems. Cathodic cleaning, in which hydrogen is deliberately evolved on the steel is clearly undesirable.

- *Electroplating* Electroplated metal coatings provide a convenient and effective means of protecting steel against atmospheric corrosion, with zinc and cadmium being particularly useful because of their ability to provide sacrificial protection to the steel substrate at breaks in the coating. Unfortunately, all metal deposition processes require the application of potentials at which hydrogen evolution is possible (in theory it would be possible to deposit copper and more noble metals above the hydrogen evolution potential, but as this would also be a potential at which iron would dissolve anodically, this would not produce good deposits). Thus, the electrodeposition of coatings almost inevitably introduces hydrogen into the metal. The majority of electrodeposited coatings on iron are much less permeable to hydrogen than iron, the major exceptions to this being other *bcc* metals, with chromium being the only example in widespread use (although even here chromium is generally used with an undercoat of nickel or copper, which will act as a barrier). Consequently, most of the hydrogen uptake occurs in the early stages of the deposition process, before a complete coverage of the coating metal has been achieved, and the start of the deposition process is particularly critical in determining the amount of hydrogen absorbed. Clearly, the highest possible ratio of metal deposition rate to hydrogen generation rate is required in this period, and this tends to be favored by high current densities. For this reason (among others), a high current density 'flash' deposit of metal is often used as the first stage of a two-stage plating scheme. Bath composition is also important in controlling the entry of hydrogen into the steel.

Once high-strength steel components have been electroplated, it is possible (and often mandatory) to reduce the damaging effects of the hydrogen by baking at  $\sim 200^\circ\text{C}$ . In part, this serves to allow hydrogen to diffuse through the coating and out to the atmosphere, but the redistribution of the remaining hydrogen within the steel, reducing damaging local high concentrations, is probably also an important part of this de-embrittlement treatment.

A very important area of use for electroplated high-strength steels is fasteners and other high stress components in aircraft. These are generally protected by cadmium plating, although the toxicity of cadmium and its compounds is giving rise to a search for alternatives. In this application, the avoidance of hydrogen embrittlement is clearly essential, and as a result, a

wide range of standard procedures and tests for cadmium plating of high-strength steels are available as civil or military specifications and codes of practice.<sup>15</sup>

- **Phosphating** Phosphating, which is widely used as a pretreatment for steel prior to painting, involves the controlled corrosion of the steel in acid solution, and inevitably leads to the uptake of hydrogen. By limiting the free acid in the phosphating bath, and by introducing oxidizing agents to raise the working potential, the uptake of hydrogen may be reduced.
- **Painting** Conventional paints are normally innocuous, but it seems possible that some modern water-based paints, particularly those applied by cathodic electrophoresis, may introduce significant quantities of hydrogen into the steel. Fortunately, these paints are generally stoved after application, and this is effective in removing the hydrogen, which permeates very easily through the paint film.<sup>16</sup> Additionally, these paints are applied primarily to lower-strength steels in motor vehicle bodies and similar applications, and as far as the author is aware, no problems have been experienced in service. However, suitable tests would be advisable if it is intended to use these processes with high-strength steels.

Paint strippers may give rise to hydrogen entry into steel, and in critical applications, such as the treatment of aircraft components, commercial paint strippers should be tested before use.

- **Corrosion in Service** Most of the modes of hydrogen entry discussed above involve a single brief charging period, and as a result are treatable, in that the hydrogen can be removed by a suitable de-embrittlement treatment (provided the embrittlement is not so severe that cracks are formed before the de-embrittlement treatment can be applied). In contrast, the entry of hydrogen due to corrosion in service is generally continuous. Thus, de-embrittlement is not feasible, and the control of hydrogen embrittlement of high strength steels presents a much more difficult problem.

In general, hydrogen will enter steel during any corrosion process involving hydrogen ion or water reduction as one of the cathodic reactions. It is frequently implied that the applied potential must be below the equilibrium potential for hydrogen evolution before hydrogen entry into steel is possible. However, for two related reasons this is not true. Firstly, the

equilibrium potential for hydrogen evolution at a given pH is that potential at which protons or water molecules at the metal–solution interface are in equilibrium with molecular hydrogen at a partial pressure of one atmosphere. As the partial pressure of hydrogen is reduced, so the equilibrium potential will increase, in accordance with the Nernst equation, and even at potentials of 200 mV above the 1-atm equilibrium potential, there will be a significant concentration of hydrogen at the metal surface. Secondly, for high-strength steels, the matrix concentration of hydrogen required to cause embrittlement is very small, as the hydrogen tends to concentrate at phase boundaries and other trap sites. Thus, hydrogen embrittlement has been observed in high-strength steel in contact with gaseous hydrogen at pressures below one thousandth of an atmosphere.

A second difficulty in predicting the effect of particular corrosion conditions on the rate of hydrogen uptake by steel is the strong influence of local conditions. For passive steel, where the corrosion potential is several hundred mV above the 1-atm hydrogen equilibrium potential, one would not expect problems of hydrogen embrittlement, and this is frequently used as an argument against a hydrogen embrittlement mechanism of SCC in environments such as phosphates and carbonate/bicarbonate. However, the local environment in pits, cracks, or crevices may be very different from conditions at the free surface. In particular, acidification may occur due to metal–ion hydrolysis (especially for chromium-containing steels), and the potential in the localized corrosion cavity may be considerably more negative than that measured at the free surface. The net result is that the conditions within the cavity may be favorable for hydrogen evolution, even though the free surface conditions imply that hydrogen embrittlement is very unlikely.

In neutral saline environments, such as seawater, the rate of hydrogen entry is controlled by (among other things) the applied potential. In this case (and probably many others) the response observed, even at a smooth surface, is not as simple as might be expected, largely because of changes in the chemistry of the liquid in immediate contact with the steel. This is indicated in **Figure 5** due to Barth *et al.*,<sup>17</sup> which shows the rate at which hydrogen permeates through a steel membrane in response to a range of applied potentials. Note that hydrogen enters steel in aerated solution when it is anodically polarized to well above the nominal equilibrium potential for hydrogen ( $\sim -650$  mV versus SCE for this near-neutral

**Figure 5** Hydrogen permeation current as a function of applied potential, showing effect of oxygen concentration and applied potential. Reproduced from Barth, C. F.; Troiano, A. R. *Corrosion* 1972, 28(7), 259–263.

solution). Similar behavior has been observed in work that has taken account of the shielding effect of a crack or crevice<sup>18</sup> and this has shown that the effects of applied potential can be explained on the basis of the local potential and pH in relation to the hydrogen equilibrium potential. Figure 6 shows typical results obtained in this work, and it can be seen that the hydrogen overpotential and the rate of hydrogen entry into the steel increase with both anodic and cathodic polarization. Detailed prediction of the effect of applied potentials on the rate of hydrogen entry require very careful consideration of many factors, including the exact composition of the solution (especially with respect to the oxygen concentration), the geometry of the component (especially the presence of any cracks or crevices), and the mass transport conditions. In general terms however, when considering the performance of steel in seawater, it seems probable that slight cathodic polarization to  $\sim -750$  or  $-800$  mV (SCE) may reduce the rate of hydrogen entry compared to free corrosion conditions, because the increased pH obtained as a result of the cathodic polarization outweighs the lowered potential. Further decrease in potential increases the rate of hydrogen entry down to  $\sim -1200$  mV (SCE), when electrochemical desorption takes over as the second stage of the hydrogen evolution reaction, and at potentials that are more negative, the rate of hydrogen entry remains roughly constant.

In deaerated neutral salt solutions, anodic polarization of chromium-free steel tends to lower the rate of hydrogen entry, as the fall in pH due to ferrous ion hydrolysis is relatively limited, and cannot compensate for the more positive potential. However, in aerated solution, the ferrous ion can be oxidized to ferric in solution by dissolved oxygen, and as ferric hydroxide is much less soluble than ferrous hydroxide, the pH can fall much lower. (This reaction is a serious problem when trying to measure the solution pH in cracks and crevices, and much of the early work which shows very acid pH values in cracks in carbon steels is now known to be incorrect because this reaction was allowed to occur between extracting the crack solution and measuring its pH). In addition to lowering the surface pH, it seems possible that the precipitated film of ferric hydroxide/oxide also presents an ohmic resistance, and may thereby allow the surface potential to become lower than that measured in the bulk solution. It seems probable that the combination of these two effects was responsible for the increase in permeation current observed for anodic polarization by Barth *et al.*<sup>18</sup> Many steels contain small, but significant concentrations of chromium, and it should be appreciated that chromium concentrations of  $\sim 1\%$  can markedly increase the tendency for local acidification, owing to the much stronger tendency for chromium ion hydrolysis.

As considerations such as those discussed above have become more widely appreciated, it has become

**Figure 6** Potential and pH in a simulated crevice, and effect on hydrogen permeation current. Reproduced from Taqi, E. A.; Cottis, R. A. *Corrosion Chemistry within Pits, Cracks and Crevices*; Turnbull, A.; NPL: London, 1987; 483–494.

clear that it is quite difficult to specify aqueous environments in which hydrogen entry into steel will occur at a sufficiently low rate that the possibility of hydrogen embrittlement can be discounted. The main candidates for such an environment are strong alkalis and highly oxidizing environments, such as nitric acid or nitrates, which are free of species, such as chloride, which predispose to pitting or crevice corrosion, and high temperature environments, such as water at 250 °C (since the deleterious effects of dissolved hydrogen decrease at high temperatures).

## 2.10.7 Effect of Hydrogen on Mechanical Properties

### 2.10.7.1 Elastic Constants

While there is some evidence of small changes in the elastic properties of steel as a result of dissolved

hydrogen<sup>19</sup> these changes are small, and of little practical consequence. This is perhaps to be expected in view of the very low solubility of hydrogen in the iron lattice and the small effect on the metal–metal bond strength.

### 2.10.7.2 Yield Stress

The effect of hydrogen on the yield stress of iron and steels is unpredictable. For very pure iron single crystals and polycrystals, the yield stress is frequently found to be decreased by hydrogen, but it may increase or stay the same, depending on the dislocation structure, crystal orientation, and purity of the iron.<sup>20</sup> Little information is available for steels.

### 2.10.7.3 Plastic Behavior

The effect of hydrogen on the plastic behavior of iron and steel is somewhat complex, as hydrogen may

harden or soften the material, according to its structure and the mode of slip. On the basis of work on single crystals of pure iron, Lunarska<sup>20</sup> has concluded that segregation of hydrogen around dislocations decreases their elastic stress fields. At room temperature (where the rate of diffusion of hydrogen is sufficiently high that it can keep up with a moving dislocation), this leads to a softening of single crystals when only one slip system is operative. The hydrogen also suppresses cross-slip of screw dislocations, and this results in increased work hardening when multiple slip systems are active. Lunarska also notes that “the presence of residuals (even at very low concentration) can drastically change all of these effects.”

It is partly because of the variable effect of hydrogen (giving both softening and hardening, according to the nature of the slip) that the extrapolation of model experiments on very pure iron to predict the behavior of commercial materials is so difficult. It is further hindered by the ability of dissolved hydrogen to modify the dislocation structure of a straining material.

### 2.10.8 Hydrogen Embrittlement of Steels

By far the most important impact of dissolved hydrogen on the mechanical properties of steels and particularly high-strength steels is the production of apparently brittle fracture where the steel would normally behave in a ductile fashion. If a steel contains dissolved hydrogen, this can result in immediate

fracture at stresses approaching the fracture stress in the absence of hydrogen, or it may result in delayed failure at lower stresses (Figure 7). The latter behavior is most pronounced for tensile tests on notched or precracked specimens, as the stress field around the notch or crack creates a high triaxial stress which dilates the metal lattice and tends to attract hydrogen from other parts of the specimen.

Some typical properties of common steels when exposed to environments supplying hydrogen are presented in Table 2. This table is presented to illustrate the order of magnitude of hydrogen embrittlement effects, and it is important to appreciate that the heat treatment and mechanical processing of a particular material, as well as the exposure conditions, can markedly affect its resistance to hydrogen embrittlement. Many of the data presented in this table have been extracted from the reviews of Sandoz<sup>21</sup> and McIntyre.<sup>22</sup> One useful fact that is indicated by the data in Table 2 is the good hydrogen embrittlement resistance of maraging steels when used somewhat below their ultimate capability. These data also illustrate the general result that a given steel will usually have a greater susceptibility to hydrogen embrittlement as it is tempered to a higher strength.

The effect of strength of the embrittlement can be rationalized by considering the changes in the size of the plastic zone at the crack tip as a function of the yield strength. The stress ahead of a perfectly sharp crack is proportional to  $1/r$ , where  $r$  is the distance from the crack tip. This goes to infinity as  $r \rightarrow 0$ , so there must be a plastic zone ahead of the crack that has yielded. The size of this plastic zone will be

**Figure 7** Typical results of static load tests on notched specimens.

**Table 2** Typical properties of common high-strength steels in salt solutions

Material	Yield stress (MPa)	Failure time <sup>a</sup> (h)	$K_{Ic}$ (MPa√m)	$K_{ISCC}$ (MPa√m)	Plateau velocity (m s <sup>-1</sup> )
HY130	900	NF	130–170	60–140	$5 \times 10^{-8}$
300M	1600	40–150	—	115	$10^{-8}$
4340	1400–1800	—	—	20	$10^{-5} - 10^{-2}$
4340	<1400	—	—	30–80	
4130	1300	—	—	30	$10^{-6} - 10^{-4}$
4130	1050	—	—	120	
18Ni MS	1900	400	40–100	5–35	
18Ni MS	1500	10,000	180	40–100	
18Ni MS	1200	NF	160	120	$10^{-5}$

<sup>a</sup>The failure time presented is the approximate time to failure at an applied stress of 75% of the yield stress of the material.  
MS = Maraging Steel.

approximately inversely proportional to the yield stress, and the peak stress will be equal to the yield stress. This discussion oversimplifies the stress state ahead of the crack tip, which is three dimensional and rather complex. However, the general conclusion is accurate. Thus, a higher strength material will have a smaller plastic zone with a larger stress in it, both the factors tend to increase the tendency for hydrogen to concentrate in this region and to cause fracture.

### 2.10.9 Hydrogen Embrittlement of Other Alloys

While the majority of work on hydrogen embrittlement is concerned with high strength steels, many other alloys have been shown to suffer embrittlement by hydrogen. We can list a few general factors that have a strong influence on typical susceptibility to hydrogen (though, like most generalizations, there will be exceptions):

- Susceptibility increases as the yield strength increases. This is an almost inevitable consequence of the reduction in the volume of the crack tip plastic zone and the increase in stress within that zone as the yield strength increases.
- Face-centered cubic (*fcc*) alloys are less susceptible than body-centered cubic (*bcc*) alloys. There are several reasons for this, (1) the greater inherent ductility of *fcc* alloys; (2) the much lower diffusion coefficient for hydrogen in *fcc* structures; and (3) the much greater solubility of hydrogen in *fcc*.
- Hexagonal close-packed (*hcp*) alloys might be expected to have an intermediate susceptibility between *fcc* and *bcc*, having lower inherent ductility than *fcc* but comparable hydrogen solubility and diffusion coefficient. However, many of the common

*hcp* alloys (Ti, Mg, Zr among others) form stable hydrides, and are therefore susceptible to hydrogen embrittlement by a hydride cracking mechanism.

It is sometimes stated that *fcc* alloys (such as austenitic stainless steels) are immune from hydrogen embrittlement. However, this is an overstatement; it is more accurate to say that they are more resistant, which typically means that more hydrogen, and/or a longer time are necessary for fracture to occur. Thus, hydrogen embrittlement has been observed in nickel sheet (used in the author's laboratory as a cathode in an electrochemical machining cell), high strength aluminum alloys,<sup>23</sup> and austenitic<sup>24</sup> and duplex<sup>25</sup> stainless steels. There are relatively few reports of hydrogen embrittlement of copper or copper-based alloys, but this is probably due to the noble character of copper, which means that hydrogen cannot be produced at a significant concentration by corrosion of copper, rather than to any inherent immunity from embrittlement.

### 2.10.10 The Influence of Microstructure and Composition

The influence of the composition and metallurgical structure of steels on their susceptibility to hydrogen embrittlement have been discussed from a theoretical basis by Bernstein and Pressouyre.<sup>6</sup> They considered the nature of the various trap sites in the steel, both with respect to their tendency to accumulate hydrogen, and their sensitivity to fracture in the presence of hydrogen. This approach seems to offer considerable potential in respect of designing alloys for hydrogen resistance without sacrificing other properties, although with our current knowledge the methods are probably more relevant for the rationalization of results.

As a general rule, the damage due to dissolved hydrogen tends to become more severe as the strength of the steel increases. In part, this may be associated with the greater resistance of the stronger material to plastic deformation, which facilitates the transition to brittle behavior. In addition, the size of the crack tip plastic zone, which defines the size of the region to which hydrogen is attracted, is inversely proportional to the yield strength of the material. Hence, for the stronger steels, a given amount of dissolved hydrogen will be concentrated into a smaller region, and will, therefore, have a more damaging effect. However, this general effect of strength level does not explain all aspects of hydrogen embrittlement of high strength steel, and steels with the same mechanical properties may be affected by hydrogen in quite different ways as a result of their different microstructures.

A particularly important aspect of the microstructural state of the steel is the condition of the grain boundary. As noted in [Section 2.10.4](#) above, 'pure' grain boundaries do not act as major sites for the trapping of hydrogen, but it is clear that impurity segregation and carbide precipitation at the grain boundary may significantly modify its behavior. Thus, it is now widely recognized that there is a strong link between various forms of temper embrittlement and hydrogen embrittlement, and quite small changes in tempering treatment can give large variations in hydrogen embrittlement resistance.<sup>26,27</sup>

On a more positive note, it seems clear that steels can be made more resistant to the effects of hydrogen by incorporating as many strong, finely dispersed traps in the microstructure as is possible, while ensuring that there are no continuous trap sites (such as embrittled grain boundaries). This may explain the better resistance of steels hardened by cold-working compared to quenched and tempered steels.<sup>28</sup> Whatever the reason, this effect is particularly fortunate in the production of prestressed concrete, where cold-drawn pearlitic (or 'patented') wires give high strength levels (~1700 MPa) with good (though not complete) resistance to hydrogen embrittlement. In this particular case, it is probably also important that most of the phase boundaries in the structure lie parallel to the tensile axis, allowing them to collect large quantities of hydrogen without serious detriment to the performance of the wire. When such wires do suffer from hydrogen embrittlement, they exhibit a characteristic elongated 'green-stick' fracture.

Similarly, it seems that retained austenite may be beneficial in certain circumstances<sup>29</sup> probably because the austenite acts as a barrier to the diffusion

of hydrogen, although in high concentrations (such as are obtained in duplex stainless steels) the austenite can also act as a crack-stopper (i.e., a ductile region in the microstructure which blunts and stops the brittle crack).

### **2.10.11 Theories of Hydrogen Embrittlement**

Despite the major technical importance of hydrogen embrittlement, and the wealth of research work on the subject, the mechanism (or perhaps mechanisms) of hydrogen embrittlement remains uncertain. Much of the book edited by Oriani, Hirth, and Smialowski is concerned with mechanistic aspects of hydrogen embrittlement, and the reader is referred in particular to the summary by Thomson and Lin.<sup>30</sup>

In considering hydrogen embrittlement mechanisms, it is important to keep in mind the concentration of hydrogen in the steel, as matrix concentrations are very low, typically of the order of one atom of hydrogen for every  $10^6$  iron atoms. It is very difficult to see how such small amounts of hydrogen can modify fracture properties so markedly, and it must be supposed that hydrogen present in traps or possibly in surface layers (where the solubility may be markedly increased)<sup>6</sup> is the main cause of embrittlement. Thus, realistic mechanisms of hydrogen embrittlement will be based on the effect of hydrogen on dislocation behavior, on the effect of hydrogen at phase boundaries or grain boundaries or on the effect of hydrogen at the metal surface. These factors will be assisted by the concentration of hydrogen to the region of triaxial tensile stress ahead of the crack.

In considering the various theories, it is also apparent that many of them may be considered as alternative descriptions of essentially the same physical process, or as descriptions of parallel processes which collaborate in the failure. Thus, a complete description of hydrogen embrittlement in a given situation will almost inevitably incorporate aspects of several of the following theories.

#### **2.10.11.1 The Pressure Theory**

The earliest theory of hydrogen embrittlement was probably the planar pressure theory advanced by Zappfe<sup>31</sup> in 1941. This essentially proposes that the effect of hydrogen is to create very high pressures of hydrogen gas in voids and other defects within the metal thereby assisting in the fracture of the steel.

While this is an important aspect of the blistering of steel by HIC, it cannot by itself explain the hydrogen embrittlement of high strength steels, where fracture may occur in steel in equilibrium with hydrogen at very low pressures.<sup>32</sup> Some concentration of hydrogen may occur as a result of dislocation transport, but it is difficult to see how significant internal pressures can be generated by hydrogen entering from an external pressure of one thousandth of an atmosphere, yet this can cause hydrogen embrittlement.

### 2.10.11.2 Decohesion Theories

The decohesion models proposed by Troiano, Oriani, and others<sup>33–35</sup> suggest that the role of hydrogen is to weaken the interatomic bonds in the steel, thereby facilitating grain boundary separation or cleavage crack growth. In view of the very low hydrogen concentration in the matrix, it is necessary for some method to exist by which the hydrogen can be concentrated at the site of the fracture. For cracking along phase or grain boundaries, this can be explained in terms of the trapping of hydrogen at the phase boundary. It is a little more difficult to see how transgranular cracking can be explained; processes which have been invoked include the concentration of hydrogen at the region of triaxial tensile stress at the crack tip and local high concentrations of hydrogen being generated by reaction or adsorption at the crack tip.

### 2.10.11.3 Surface Energy Theories

Surface energy theories were first proposed by Petch and Stables.<sup>36</sup> By lowering the surface energy of the newly formed crack, the hydrogen reduces the stress intensity required for brittle fracture. As with the decohesion models, surface energy models only seem reasonable for the case of hydrogen derived from surface layers or grain boundaries, since the hydrogen adsorption must occur at the same time as the fracture event in order for the reduction in surface energy to be effective in lowering the energy required for fracture.

### 2.10.11.4 Hydride Formation

In some systems, notably titanium alloys, hydrogen embrittlement has been attributed to the formation and subsequent fracture of brittle hydride phases at the crack tip. This has been postulated by Gahr *et al.*<sup>37</sup> as a mechanism of hydrogen embrittlement of niobium. While there is little evidence for hydride

formation in steels, it can be argued that hydrides would be unstable and would dissolve as soon as the crack has propagated through them. In view of recent evidence of significant structural rearrangement of steel surface containing chemisorbed hydrogen,<sup>6</sup> the possibility should also be considered of the induction of cleavage by a brittle surface film, similar to the film-induced cleavage model of stress corrosion cracking.<sup>38</sup>

### 2.10.11.5 Local Plasticity Theories

Various workers have suggested that hydrogen acts by reducing the stress required for dislocation motion. This follows observations by several workers (summarized by Morgan and McMahon<sup>39</sup>) of enhanced dislocation motion in thin films exposed to hydrogen. Similarly, Lynch<sup>40</sup> found very similar fractography for liquid metal embrittlement and hydrogen embrittlement, and proposed that both processes involve the facilitation of dislocation emission at the crack tip. Lynch,<sup>3</sup> echoing the earlier review of Birnbaum *et al.*,<sup>2</sup> describes the three currently favored mechanisms:

- hydrogen-enhanced localized plasticity (HELP);
- hydrogen enhanced decohesion (HEDE); and
- adsorption-induced dislocation emission (AIDE).

In the HELP mechanism, crack propagation occurs by highly localized slip due to local softening by hydrogen at the crack tip. HEDE is due to weakening of the metal-metal bond allowing brittle fracture rather than plastic deformation (essentially this is the decohesion model described above). AIDE is described by Lynch as "... based on hydrogen induced weakening of interatomic bonds (as for HEDE) but with crack growth occurring by localized slip (as for HELP)." The corrosion-enhanced plasticity model proposed by Delafoss and Magnin<sup>41</sup> is rather more general description of an essentially similar model to HELP, in that the enhanced plasticity may be due to corrosion, as well as hydrogen, effects.

### 2.10.12 Hydrogen Embrittlement Tests

There are several classes of test for hydrogen embrittlement, according to the application. Three general types of mechanical test can be identified, together with chemical and electrochemical tests intended to determine the hydrogen content of steels or the rate of entry of hydrogen from an environment.

### 2.10.12.1 Constant Stress Tests

The simplest test for hydrogen embrittlement involves applying a constant stress to a specimen. This can be applied both to the testing of samples which already contain hydrogen (e.g., as a result of electroplating) and to the testing of samples in environments causing hydrogen entry. The specimen may take various forms but is commonly a tensile specimen. Particularly where the test is being used to examine the effect of dissolved hydrogen which is already present in the steel, the specimen may be notched, in order to develop a region of triaxial stress at the tip of the notch that will tend to concentrate hydrogen.

When a constant stress test of a notched specimen is being used for the evaluation of samples containing hydrogen, it is commonly referred to as a sustained load test, although the terms stress rupture and static fatigue are also used in the older literature. The results of a typical sustained load test are shown in **Figure 7**. At a stress which is frequently (though not necessarily) below the notch tensile strength for hydrogen-free material, the specimen will fail instantaneously as a result of the damaging effect of the uniform hydrogen concentration in the steel. At lower stresses, delayed failure occurs as hydrogen diffuses to the region of triaxial stress at the tip of the notch. Eventually, as the stress is reduced, the quantity of hydrogen in the neighborhood of the notch is insufficient to cause failure, and a critical or threshold stress is reached. The behavior of a steel sample in this test is a function of both the material and the hydrogen concentration, with an increase in hydrogen concentration giving instantaneous failure at lower stresses, shorter times to failure, and a lower critical stress. Testing at lower temperatures will give longer failure times, since the rate-controlling process is hydrogen diffusion, but the critical stress will go down, as the intrinsic tendency of the steel to brittle rather than ductile failure is increased. At elevated temperatures, hydrogen may be lost by degassing and by trapping, and in this case, the critical stress will increase. The failure stress is also strongly influenced by the notch tip radius, with a smaller radius giving shorter times to failure and failure at lower stresses. This can be explained in terms of the size and intensity of the region of triaxial stress at the notch tip, with a sharper notch giving a smaller triaxial region, which can develop a higher hydrogen concentration in a given time. Because of the difficulty of obtaining a reproducible notch tip geometry, the sustained load test tends to give rather scattered results. Smooth specimens can be used for sustained

load testing, but in this case, the defects responsible for local hydrogen concentration will typically be surface or near-surface nonmetallic inclusions, and the chance organization of these will give highly scattered results. Smooth specimen results will also tend to be nonconservative, as the majority of real components are liable to contain stress concentrators of one form or another.

In addition to testing for the effects of preexisting hydrogen in the steel, sustained load tests can also be used to test for the effect of hydrogen entering from the environment. Both smooth and notched specimens can be used. At short times, the results obtained will differ from those for steels containing dissolved hydrogen, since time will be required for the hydrogen to enter the steel. However, this time can be very short, since hydrogen can diffuse  $\sim 10\text{ }\mu\text{m}$  in 1 s, and failure times of the order of seconds can be obtained for severe environments and loading conditions. For tests at ambient temperature, it is found that the critical stress is reached fairly quickly, and it is generally found that failures will occur within a month of exposure of the samples. This provides something of a problem in relating service behavior to laboratory tests, since service failures are often observed after much longer exposure times. This may be a result of variations in exposure conditions in service or it may be associated with the need to develop initiating defects by pitting corrosion or similar processes. Whatever the cause, it does lead to the conclusion that sustained load tests cannot be used to predict service life with any accuracy.

### 2.10.12.2 Controlled Strain-Rate Tests

Controlled strain-rate tests were first developed by Parkins<sup>42</sup> for the study of stress-corrosion cracking. These took the form of constant strain-rate tests (also known, perhaps more accurately, as constant extension rate tests). Since then alternative forms of test have been developed to modify the conditions under which the specimen is exposed.

The slow strain-rate test is based on the principle that stress corrosion cracking processes are normally dependent on plastic strain in the material. By extending the specimen very slowly, any stress corrosion cracking phenomena are given every possible opportunity to occur, hence, the slow strain-rate test can quickly reveal any tendency to cracking in a given metal–environment combination. A particular advantage of the slow strain-rate test is that failure of the specimen will always occur in a reasonable time, if

only by normal ductile fracture processes. Test durations clearly depend on the strain-rate and the ductility of the metal, but typical test durations for steels in hydrogen embrittling environments are  $\sim 1$  week. In addition to providing a rapid indication of the possibility of SCC in a particular system, the slow strain-rate test can also be used to study the effect of material and environmental factors on the susceptibility. For example, **Figure 8** shows the effect of environment composition and tempering temperature on the reduction in area obtained for tests on a quenched and tempered steel in various aqueous solutions. The minimum in the reduction in area which can be seen for tempering temperatures of  $350^\circ\text{C}$  provides evidence of the interaction between hydrogen embrittlement and temper embrittlement.

While the conventional slow strain-rate test offers many benefits, it does suffer from a tendency to overstate the susceptibility of materials to hydrogen embrittlement. Thus, structural steels of modest strength will fail even under conditions giving relatively low rates of hydrogen entry. This is because the enforced plastic deformation provides a very severe test condition, which may not be reproduced in service when

relatively low stresses are applied to components. This problem is partly addressed by the sustained load test, but this may be unduly mild, as there will be no plastic strain in the specimen once the initial creep strain has died away. In order to provide a test with intermediate severity, Erlings and his co-workers<sup>43</sup> developed a test which exposes the specimen to a quasi-constant strain-rate, but at the same time keeps the specimen within the elastic range. This involves prestraining a slow strain-rate specimen up to the yield stress. Then the specimen is exposed to a regular cycle, the stress being reduced (typically) to 90% of the yield stress, slowly strained to 95% of the yield stress, then dropping back to 90%. This test is proposed as a part of a sequence of tests, starting with the low-cost slow strain-rate test, for the qualification of materials for service, as indicated in **Figure 9**.

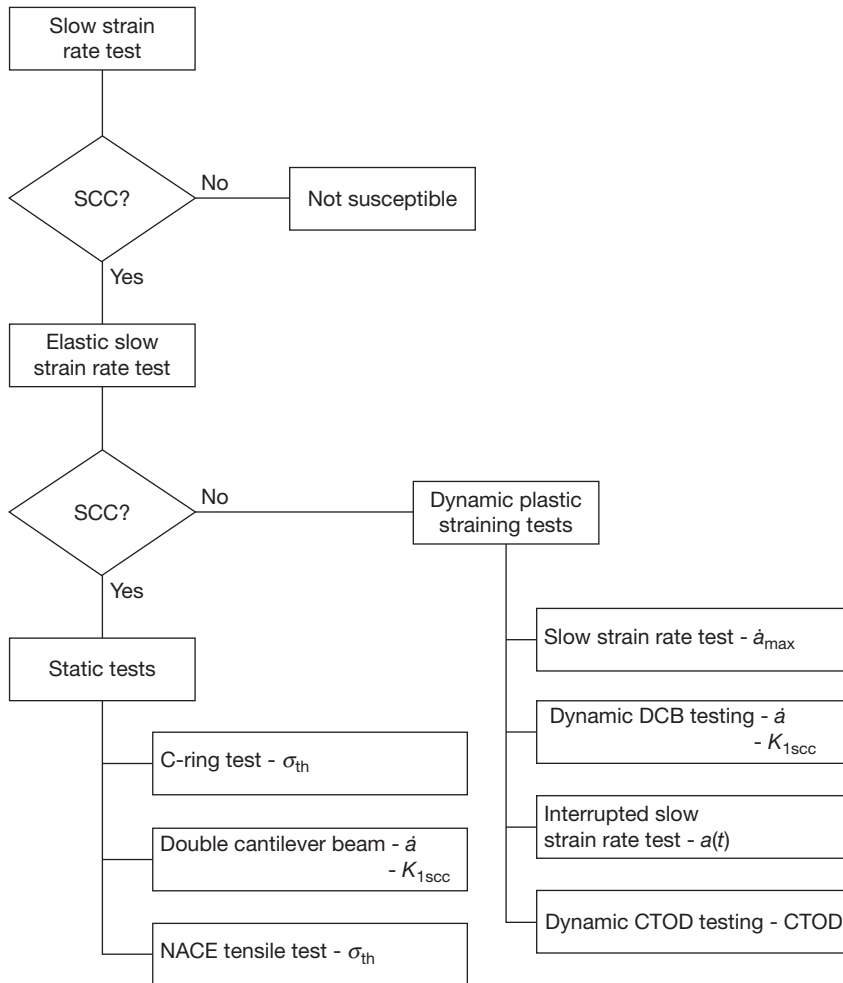

Another modification to the slow strain-rate test involves the superimposition of a low amplitude sine wave ripple on the slow uniform extension (**Figure 10**). In effect, this produces higher strain-rates (which appear to be more damaging for hydrogen embrittlement), while still giving a long test duration, with adequate time for the accumulation of hydrogen in the steel.<sup>44</sup>

**Figure 8** Variation of reduction in area as a function of tempering temperature. Reproduced from Johnston, J. W.; Cottis, R. A.; Procter, R. P. M. *Electrochem. Soc. Extended Abstracts* 1987, 87(2), 454–455.

### 2.10.12.3 Fracture Mechanics Tests

One problem of both sustained load and slow strain-rate tests is that they do not provide a means of predicting the behavior of components containing defects (other than the inherent defect associated with the notch in a sustained load test). Fracture mechanics provide a basis for such tests, and measurements of crack velocity as a function of stress intensity factor,  $K$ , are widely used. A typical graph of crack velocity as a function of  $K$  is shown in **Figure 11**. Several regions may be seen on this curve. At low stress intensity factors, no crack growth is observed until a threshold stress intensity factor,  $K_{\text{ISCC}}$  is reached. Typically,  $K_{\text{ISCC}}$  is fairly insensitive to the rate of hydrogen entry into the steel (as the crack is not growing at a significant rate, hydrogen will eventually accumulate at a sufficient concentration at the crack tip, whatever the rate of entry). As the stress intensity factor increases above  $K_{\text{ISCC}}$  the crack growth rate increases rapidly, until a plateau crack velocity is attained. The plateau velocity is a function of the rate of hydrogen entry, and the plateau is usually attributed to the availability of hydrogen at the crack tip being the rate-limiting factor. Finally, the crack velocity increases again as the stress intensity factor approaches the critical stress intensity factor for fast fracture,  $K_{\text{IC}}$ .

**Figure 9** 'Elastic' slow strain-rate test. Reproduced from Crooker, T. W.; Hauser, J. A. H A Literature Review on the Influence of Small-Amplitude Cyclic Loading on Stress Corrosion Crack Growth in Alloys, NRL Memorandum Report 5763, Naval Research Laboratory, Washington DC, April 3, 1988.

**Figure 10** Strain-time history for 'Ripple' test (schematic).

In this region, the fracture consists partly of ductile tearing and partly of hydrogen embrittlement, with the hydrogen assisting the fracture of the tougher areas in the metal. The above discussion has assumed that the

crack is loaded in Mode I (the crack opening mode, with a tensile stress normal to the plane of the crack). Hydrogen has relatively little effect in Modes II or III, as these generate shear stresses at the crack tip, rather than tensile stresses, and the shear behavior of steels is relatively little affected by hydrogen, presumably because dilation of the lattice at the crack tip (which does not occur in Modes II and III) is required for hydrogen accumulation.

### 2.10.13 Controlling Hydrogen Embrittlement in Service

Clearly there are two major ways in which hydrogen embrittlement can be controlled in service – either the hydrogen content of the steel can be reduced

**Figure 11** Stress-corrosion crack velocity as a function of applied stress intensity factor.

(by limiting the rate of entry or by baking to remove existing hydrogen), or the steel can be made more resistant to hydrogen.

### 2.10.13.1 Reduction of Hydrogen Content

Preexisting hydrogen in steel, introduced by electroplating or other processing, can be reduced by a suitable de-embrittlement treatment, as discussed above. A more difficult problem is the limitation of hydrogen entry in service. The feasibility of controlling hydrogen embrittlement in this way will clearly depend on the application, and in particular on the source from which the hydrogen is entering the steel. Thus, hydrogen pickup from acid pickling can be reduced by the use of appropriate inhibitors, and de-embrittlement treatments can be used after pickling. In contrast, hydrogen entry into components in an electrical generator using hydrogen as the cooling gas cannot easily be modified.

In general preventing the entry of hydrogen from the gas phase is liable to be difficult. Inhibition is possible, for example, small quantities of oxygen can markedly reduce the rate of hydrogen uptake, presumably as a result of blocking active sites on the metal

surface. Similarly, ethylene gas will react with adsorbed hydrogen atoms, thereby preventing them from diffusing into the steel. However, there will be few cases in which it is permissible to modify the environment in this way (adding oxygen to hydrogen will certainly cause some concern). Organic coatings will not generally be very effective in reducing hydrogen entry, since these are usually rather permeable to hydrogen. Furthermore, such coatings are usually susceptible to local damage. Metal coatings may offer some reductions in hydrogen entry, as most close-packed metals have a significantly lower diffusion coefficient for hydrogen than iron, although this is partially compensated for by a higher solubility.

In aqueous solutions, it becomes somewhat more feasible to modify the entry of hydrogen into the steel. This can be achieved by the addition of inhibitors to the solution, by control of the electrochemical potential of the metal and by coatings.

In situations such as the acid pickling of steel or the use of steel pipes to handle sour oil streams, the use of suitable inhibitors can give a significant reduction in hydrogen entry. In this context, it is important to emphasize that the efficiency of an inhibitor in reducing hydrogen entry is not the same as its efficiency in reducing corrosion. Thus, arsenic and antimony compounds are effective inhibitors of corrosion of steel in acid, but they achieve this by inhibiting the hydrogen recombination reaction, thereby increasing the rate of hydrogen entry into the steel. In contrast, the addition of chloroplatinic acid to a solution will increase the corrosion rate by accelerating the hydrogen evolution reaction. However, a part of this acceleration arises because the hydrogen recombination reaction is catalyzed by the particles of platinum which are deposited on the surface by an exchange reaction. As a result, chloroplatinic acid acts as an inhibitor of hydrogen entry. This can be seen in [Figure 8](#), where the addition of chloroplatinic acid to 3.5% sodium chloride solution has increased the reduction in area for a given heat treatment. Clearly, this is impractical for service use, but several organic inhibitors are available which are effective in reducing both corrosion and hydrogen entry into the steel.

The electrochemical potential has a direct influence on the entry of hydrogen into steel from aqueous solutions, and control of potential represents an obvious way to control hydrogen uptake. Unfortunately, the effect of potential on hydrogen entry is complex, and is strongly dependent on solution composition. For example, as has been discussed above, it has been shown<sup>18</sup> that anodic polarization of steel in salt

solution will give an increased rate of hydrogen entry in aerated solution, but negligible entry in deaerated solution. The situation becomes even more complex in passivating environments, especially where pitting or crevice corrosion can occur. As a generalization, for aerated neutral salt solutions the optimum potential for minimum hydrogen uptake appears to be slightly below typical free corrosion potentials, a typical value for seawater being  $\sim -750$  to  $-800$  mV (SCE). This potential is also sufficient to reduce corrosion rates, but it gives very little margin for potential differences over the structure being protected. Potentials much below  $-900$  mV will undoubtedly increase the rates of hydrogen entry, and in view of the hazards involved in overprotection, the deliberate application of cathodic protection to high strength steel structures is probably best avoided.

As in gaseous environments, metal coatings can reduce the rate of hydrogen entry by acting as a low permeability barrier. In addition, the coating metal may also modify the electrochemical properties at the metal–solution interface, as in the case of traces of platinum derived from chloroplatinic acid. For application in seawater and other neutral salt solutions, zinc, and cadmium probably offer the best combinations of properties, having low exchange current densities for hydrogen evolution and relatively low hydrogen permeabilities. In the event that part of the steel substrate is exposed by mechanical damage, a zinc coating has a rather low corrosion potential in seawater, and may be expected to give rapid hydrogen entry. However, cadmium gives a potential which is around that at which the minimum rate of hydrogen entry is observed, and is highly recommended as a coating material for high strength steels. Unfortunately, the toxicity of cadmium compounds precludes its use in most applications. Proposed schemes for ‘cadmium replacement’ should be examined carefully for their effect on hydrogen embrittlement as well as their corrosion performance.

Organic coatings such as paints are also effective in reducing the corrosion of steel, but as with inhibitors, it is not certain that this will also mean that the rate of hydrogen entry is reduced. Organic coatings are typically rather permeable to water, and it is possible for this to be reduced to hydrogen. Whether this hydrogen subsequently enters the steel will depend on the characteristics of the coating–steel interface, and little is known about this. It is recommended that suitable tests should be performed before using organic coatings for protection of high strength steels.

### 2.10.13.2 Increasing Resistance of Steel

For a given steel, the hardness will play a major part in determining its resistance to hydrogen embrittlement, but other factors are also significant. Thus, it is particularly important to obtain an appropriate microstructure, without any temper embrittlement or other deleterious features (see above). Where possible the use of work-hardened ferritic–pearlitic structures will probably give better performance than quenching and tempering, providing the stress is applied parallel to the working direction.

In particularly severe conditions, it may be found necessary to use austenitic steels, such as stainless steels from the 300 series. The *fcc* structure of austenite is inherently more ductile than *bcc* ferrite, and it is therefore less liable to switch to brittle modes of fracture in the presence of hydrogen. Additionally the permeability of austenitic steels is less than that of ferritic. The common commercial grades of austenitic stainless steel tend to be rather marginal in respect of the stability of the austenite phase, and they are therefore susceptible to the formation of martensite by strain-induced transformation. This martensite is susceptible to hydrogen embrittlement, and it is therefore important to ensure that steels used for hydrogen service have sufficient austenite stabilizing elements, primarily nickel. This is illustrated in Figure 12, where the effect of nickel content on the residual ductility in hydrogen is presented.<sup>45</sup> Below  $\sim 10\%$  Ni there is a strong tendency to strain-induced martensite

**Figure 12** Effect of nickel content on residual ductility of austenitic stainless steels. Reproduced from Caskey, G. R. Third International Congress on Hydrogen and Materials, Paris, 1982; p 611–616.

formation, and low residual ductilities are observed. Once the austenite becomes fully stable however, there is hardly any loss in ductility due to hydrogen.

### 2.10.13.3 Prediction of Behavior

An important aspect of the use of materials in aggressive environments is the prediction of service life, such that planned maintenance procedures can be used. A typical approach that might be suggested for steels in conditions where hydrogen embrittlement can occur is to assume a maximum possible defect in the structure, usually based on the expected capabilities of the inspection system. Using a suitable relationship for the crack velocity as a function of stress intensity factor, the time to failure is calculated by integrating from the initial defect size up to that necessary for fast fracture. While this method is attractive in theory, in practice it is liable to be rather unproductive for high strength steels. The reason for this is that typical plateau crack velocities for hydrogen embrittlement are very high (between  $10^{-6}$  and  $10^{-2} \text{ m s}^{-1}$ ), and the transition from  $K_{\text{ISCC}}$  to the plateau occurs over a rather small range of stress intensity factor. Thus, unless the initial defect happens to give a stress intensity factor fractionally above  $K_{\text{ISCC}}$ , this calculation will predict either no failure or a very short life (even  $10^{-6} \text{ m s}^{-1}$  corresponds to a crack velocity of  $3.6 \text{ mm h}^{-1}$ ). Currently, the understanding of the failure of components by hydrogen embrittlement after long periods in service remains somewhat limited, but in many cases, it seems probable that pitting corrosion plays an important part in the slow crack initiation process. Thus, prediction of life in hydrogen embrittlement conditions should be concerned with initiation processes in addition to the crack growth above  $K_{\text{ISCC}}$ , although there is not yet a sufficiently clear understanding of the initiation processes for this to be a productive exercise.

### 2.10.14 Modeling of Hydrogen Embrittlement

At a fundamental level, improvements in techniques for *ab initio* modeling at the atomic level, coupled with the continuing rapid increase in the power of high performance computers, has led to a significant improvement in our understanding of the behavior of hydrogen in metals, including aspects such as the binding energy of hydrogen to dislocations<sup>46</sup> and the segregation of hydrogen to grain boundaries.<sup>47</sup>

While it is not currently feasible to construct a completely reliable *ab initio* model of hydrogen embrittlement initiation or propagation, some moves have been made in that direction. Serebrinsky *et al.*<sup>48</sup> have developed a model of intergranular hydrogen embrittlement “based upon: (1) a cohesive law dependent on impurity coverage that is calculated from first principles; (2) a stress-assisted diffusion equation with appropriate boundary conditions accounting for the environment; (3) a static continuum analysis of crack growth including plasticity; and (4) the Langmuir relation determining the impurity coverage from its bulk concentration.” They concluded that “The calculations reproduce the following experimental trends: (1) time to initiation and its dependence on yield strength and stress intensity factor; (2) finite crack jump at initiation; (3) intermittent crack growth; (4) stages I and II of crack growth and their dependence on yield strength; (5) the effect of the environmental impurity concentration on the threshold stress intensity factor; and (6) the effect of temperature on stage II crack velocity in the low-temperature range.”

### 2.11.1 Introduction

There are several forms of environmental cracking that are either stimulated or produced by hydrogen.

Over the past decade and in previous decades, there have been a significant number of pipeline failures attributed to such mechanisms. The types of cracking and compatibility of materials will be described in this chapter.

In an ideal world, high strength steels would be fully utilized in, for example, pipelines and offshore structures, the weight advantage being very attractive. However, in general terms, as the strength of steel increases

so does the susceptibility to hydrogen embrittlement. This has been treated in the previous chapter, and only one variant of this process, which is experienced in harder welds in pipeline steels, will be discussed here.

In addition to the hydrogen embrittlement of harder steels, there are also hydrogen cracking mechanisms that occur in softer steels, such as hydrogen pressure induced cracking (HPIC), and these processes are the focus of this chapter.

Hydrogen embrittlement is clearly a function of dissolved atomic hydrogen, while HPIC clearly depends on the formation of molecular hydrogen within the steel (and hence depends on the presence of very high hydrogen fugacity). However, a crack morphology now recognized and termed stress orientated hydrogen induced cracking (SOHIC) has been defined, and modern thinking suggests that the crack mechanism is driven by a combination of atomic and molecular hydrogen. This latter crack mechanism has been and is still the subject of much research.

The three types of cracking described above have all been responsible for a significant number of pipeline and pressure vessel failures.

In an effort to provide a clear picture, the three crack mechanisms will be dealt with separately.

### 2.11.2 Sources of Hydrogen

The general sources of hydrogen have been described in the previous chapter; here we concentrate on the

production of the very high hydrogen fugacities that are necessary for HPIC and SOHIC. In order to achieve these high fugacities, it is necessary to generate hydrogen at the metal surface at an activity that would be in equilibrium with a very high partial pressure of hydrogen (far above atmospheric pressure). The only common way in which this can be achieved is by corrosion in the presence of hydrogen sulfide ( $\text{H}_2\text{S}$ ). The hydrogen sulfide may be naturally-occurring in oil and gas reservoirs (produced fluids may contain more  $\text{H}_2\text{S}$  than oil, with the highest reported  $\text{H}_2\text{S}$  content being 87%<sup>1</sup>) or from reservoir souring as a result of infection by sulfate reducing bacteria introduced during water injection.

**Figure 1** illustrates the processes that are involved in the production of hydrogen gas at the steel surface. In most environments, the vast majority of the hydrogen is evolved as gas and the amount entering the steel is very small (typically less than 1%).

The mechanism whereby the atomic hydrogen enters the steel in great quantities depends on the poisoning of the recombination reaction in which two adsorbed hydrogen atoms combine to form a hydrogen molecule that then disperses as dissolved hydrogen or as bubbles of gas. This causes the adsorbed hydrogen concentration to increase and consequently, more hydrogen enters the steel.

While several species act as poisons for hydrogen recombination,  $\text{H}_2\text{S}$  is by far the most common source of problems, largely because of its presence in oil and gas production. It is considered that the presence of the  $\text{HS}^-$  from disassociated hydrogen sulfide is the primary poison. Thus, in the presence of hydrogen sulfide, it has been estimated that more than 90% of the atomic hydrogen produced can enter the steel substrate.

It has also been suggested that the  $\text{HS}^-$  ion acts as a catalyst for hydrogen entry, and details of the mode of action of  $\text{H}_2\text{S}$  remain to be clarified. However, the facts are that in the presence of hydrogen sulfide or other

particular compounds such as cyanides, atomic hydrogen can enter steel in vast quantities, whereas under highly corrosive conditions such as corrosion in hydrochloric acid, where copious quantities of gaseous hydrogen is produced, hydrogen atoms do not enter the steel anywhere near such amounts.

### 2.11.3 Hydrogen Pressure Induced Cracking (HPIC)

This phenomenon is also called blister cracking, stepwise cracking, or simply hydrogen induced cracking (HIC). HPIC is far more descriptive as it is the pressure of hydrogen that causes the cracking as described later.

Atomic hydrogen enters the steel substrate and will continue in theory to the other side; however, the atoms collect at sites such as metal-inclusion interfaces, voids, and other crystal defects. While hydrogen is essentially insoluble in metals in a molecular form, hydrogen molecules can form at metal-inclusion interfaces, leading to the development of internal pockets of hydrogen. Further, atoms are attracted to this site, form more hydrogen molecules, and a gas pressure builds up. This pressure can reach many MPa, and eventually, the yield strength of the steel is exceeded and cracks are initiated. As more hydrogen enters the steel and further small cracks initiate, some of the cracks join together in a shear mode. These often look like steps, hence, the name stepwise cracking, see **Figures 2 and 3**.

Generation of hydrogen by corrosion processes

**Figure 1** The corrosion process.

**Figure 2** Example of HPIC in Plate Steel (courtesy Hay, M. Shell Canada).

**Figure 3** HPIC in pipeline steel (courtesy Hay, M. Shell Canada).

During the era of ‘controlled rolled plate,’ such features were not uncommon and a number of failures occurred.

Steels have now been developed with improved microstructure, achieved using calcium treatment which minimizes the inclusions and banded microstructure that are the sites for HPIC initiation. Having said that, HPIC failures are still occurring when high levels of  $H_2S$  are encountered, thus, steels for use in sour environments should be tested – see [Section 2.11.6](#).

HPIC can occur in low strength steels with hardness levels well-below the recognized level needed for hydrogen embrittlement to occur.

#### 2.11.4 Hydrogen Embrittlement

The first distinction to be made is that hydrogen embrittlement is an atomic hydrogen mechanism not a molecular hydrogen mechanism. Hydrogen embrittlement is a particular problem in the oil and gas industry in the context of welds, where higher hardness than the parent plate can be obtained, together with high residual stresses. Owing to the high hydrogen levels that can be achieved by the action of  $H_2S$ , failure can occur at somewhat lower levels than is normally found for hydrogen embrittlement. When it occurs in the presence of  $H_2S$ , the phenomenon is known as sulfide stress corrosion cracking (SSCC) or sulfide stress cracking (SSC).

In general terms, the higher the strength and hardness of a steel the higher the susceptibility to this form of cracking. The industry recognized upper hardness limit as Vickers  $HV_{10}$  248 or Rockwell ‘C’ scale 22, see [Figure 4](#).<sup>2</sup>

**Figure 4** Hydrogen embrittlement (SSCC) of Pipeline weld.

#### 2.11.5 Stress Oriented Hydrogen Induced Cracking (SOHIC)

The morphology of this type of crack is illustrated in [Figure 5](#).

This type of cracking has also been termed ladder cracking or stacked array cracking.

Pargeter has presented a documentary history of SOHIC failures<sup>3</sup>; the evidence strongly suggests that a complex or tri-axial stress condition is required to generate such cracking, in combination with a high flux of hydrogen. It is important to note that the stress can be residual rather than applied.

The first SOHIC failures occurred in spirally welded line-pipe ([Figure 6](#)). There have been a number of catastrophic bursts.

By virtue, its manufacturing process, spirally welded pipe has a high residual stress adjacent to the weld. SOHIC cracks are often positioned adjacent to the heat-affected zone (HAZ) of the weld.

SOHIC has also been identified in failures in pressure vessels, and in one case a seamless pipeline.

##### 2.11.5.1 SOHIC Mechanism

At the time of writing, there are a number of ongoing research programs to try to fully identify the SOHIC mechanism, and one to develop an acceptable test method.

It is generally considered that the following events occur: the steel is flooded with hydrogen from the corrosion process, there is a tri-axial stress, voids are generated, and small internal blister type cracks initiate by the HIC mechanism of molecular hydrogen being formed and trapped. These small cracks themselves generate internal stress fields which further attract atomic hydrogen, further small

**Figure 5** Stress-oriented hydrogen induced cracking (SOHIC).

**Figure 6** Spirally welded pipe – SOHIC failure (courtesy Shell Canada).

cracks initiate in the through thickness direction, which heightens the stress level, atomic hydrogen then leads to cracking by processes similar to those involved in hydrogen embrittlement, the resultant cracks joining up the small HIC cracks. The eventual failure is by coalescence of the through wall features.

Some workers in the field are also of the opinion that the initial cracks could be formed around small spherical inclusions. In some instances, these have been found in the center of the crack. The definitive mechanism whereby the cracks form in a vertical array is yet to be discovered.

Current research has identified the overall importance of a tri-axial stress, and a test method that applies a complex stress field to the sample is in the late stages of refinement.

It should be noted that SOHIC is not limited to line-pipe, it has been observed in plates and fittings. Interestingly, the materials in question had hardness significantly below the level accepted for SSCC/hydrogen embrittlement resistance.

## **2.11.6 Testing Methods for Hydrogen Cracking**

### **2.11.6.1 Hydrogen Pressure Induced Cracking**

An industry accepted test method has been developed and used for many years, namely NACE TM0284.<sup>4</sup> The method is quoted in many standards such as ISO 15156<sup>2</sup> and EFC publication No. 16.<sup>5</sup>

It is important to note that ISO 15156, the industry standard for sour oil and gas production, notes that all tests should be undertaken on samples representative of the final product form.

Although stress is thought not to influence HPIC, it has been noted several times by various workers that residual strain can be detrimental, as such tests on plate have shown no failure, whereas tests in pipe made from the plate have exhibited failure when the outer strain level reached 2% or more.

The test is a simple immersion test of unstressed coupons which are exposed to H<sub>2</sub>S saturated brine. After a set exposure time, the samples are metallographically examined for cracks.

### **2.11.6.2 Hydrogen Embrittlement**

Considerable further work has been undertaken since Erlings' work described in the previous chapter,<sup>6</sup> and there are now several variations in loading technique, such as interrupted slow strain and step loading slow strain rate testing.

One of the more common loading schemes is illustrated in **Figure 7**:

Further information on this type of testing can be found in ASTM F 1624-06.<sup>7</sup>

Other published test methods include:

NACE TM0177<sup>8</sup> methods A, B, C, and D; method 'A' smooth tensile, method 'B' three point bend (now largely superseded by other configurations), method 'C' ring, method 'D' double cantilever bend.

EFC 16<sup>5</sup> Four Point Bend (ASTM G39)\_Mostly applicable to Weld qualification.

NACE TM0198<sup>9</sup> Slow Strain Rate

**Figure 7** Load-time history for a cyclic slow strain rate test.

### 2.11.6.3 Testing for SOHIC

At the time of writing, there is currently no universally accepted test for SOHIC. There are two published methods, one for pressure vessel plate (NACE TM0103<sup>10</sup> the double beam test, not to be confused with the double cantilever beam test; under review for withdrawal) and one for line-pipe (HSE Publication OTI 95 635<sup>11</sup> the full ring test).

## 2.09.1 Introduction and Definitions

Stress corrosion cracking (SCC) is the gradual growth of cracks under the simultaneous influence of a nominally static stress and a chemically reactive environment. The meaning of 'nominally static' is discussed in **Chapter 2.08, Environmentally Assisted Cracking Overview** – this does not exclude slow or low-amplitude dynamic loading, or periodic unloading. It is convenient to refer to SCC as occurring under 'tensile' stress, although shear stresses certainly play a major role microscopically, and some SCC testing is done under mode III loading (antiplane shear; torsion), to confirm whether or not hydrogen is playing a

role in the cracking – hydrogen is supposed to be less aggressive under torsion because there is, nominally, no lattice dilation to increase the solubility of hydrogen. In this chapter, we restrict ourselves to metals, although interesting SCC phenomena occur in glasses and hot rocks, and are thought to be involved in major geologic upheavals.<sup>1</sup> Actually, fracture of brittle solids can be more amenable to first-principles calculations than the more complex phenomena that occur in metals, so in some ways nonmetals are at the leading edge of the subject.<sup>2</sup> Polymers and polymer–matrix composites also show environmentally assisted cracking (EAC) phenomena that some people would call SCC.

In metals, SCC cracks are normally multiple, branched, and either intergranular, or transgranular and cleavage-like (see **Chapter 2.08, Environmentally Assisted Cracking Overview**, for examples). Sometimes the two modes coexist, or transgranular SCC occurs simultaneously with intergranular corrosion – **Figure 1**. This fractography, when examined in sufficient detail, continues to provide important clues to the cracking mechanism, whether in the laboratory or in the field.<sup>3,4</sup> In particular, transgranular SCC facets are close to a particular fracture plane, for example, {110} in  $\alpha$ -brass, but have ultrafine detail indicative of the operation of plastic processes on the nanometer scale.

SCC can be considered a 'brittle' mode of failure, in that the material fails to manifest its usual tensile strength and ductility. But SCC is always accompanied by microscopic plastic strain, and many believe that such strains, occurring dynamically at the crack tip, are a causal factor of crack growth.

It is easier to pose the question – what kinds of EAC are not SCC – than to list pedantically what is SCC. So, hydrogen-induced cracking of a high-strength steel due to gaseous hydrogen, or to excessive cathodic protection, is not SCC. But cracking of the same material in saltwater under free corrosion conditions is SCC, even if we are 100% sure it is due to hydrogen released by the corrosion process. Liquid metal embrittlement (LME) is not SCC. Cracking of high-strength steel in dry gaseous chlorine<sup>5</sup> is SCC, but cracking in dry gaseous  $H_2S$  might be too obviously a hydrogen effect to be SCC. Cracking of carbon steel in anhydrous liquid ammonia is certainly SCC. Cracking of alloys in air at very high temperatures where dry oxidation and creep are both possible could, arguably, be called SCC,<sup>6</sup> although such phenomena have other names such as oxygen embrittlement. But despite these nonaqueous

**Figure 1** SCC of Monel 400 in copper sulfate solution, showing intergranular corrosion/SCC and transgranular SCC. Reproduced from Barnes, A.; Deakin, J.; Newman, R. C. *Corrosion* **2007**, 63, 416–418.

examples, the vast majority of SCC is caused by some combination of water, oxidant, and ions or soluble molecules. And like other forms of corrosion, most SCC can be retarded or prevented by removing oxygen.

The velocity of SCC (crack growth rate) can be as high as  $10^{-5} \text{ m s}^{-1}$  or as low as  $10^{-12} \text{ m s}^{-1}$ . Common practical rates are in the range  $10^{-11}$ – $10^{-8} \text{ m s}^{-1}$  – roughly, 1  $\mu\text{m}$  to 1 mm per day. In real components, cracking is often intermittent, occurring during start-ups or other plant transients, which can make the apparent or average crack velocity very low indeed.

The consequences of SCC are quite different in low-strength and high-strength alloys. In a high-strength material, stresses are usually externally imposed, and growth of a stress corrosion crack can lead to catastrophic rupture when the fracture toughness is exceeded, whereas in low-strength materials, the dominant stresses are often internal (residual), and SCC causes leakage or gradual plastic tearing.

The history of SCC has often been told, and will be mentioned quite briefly. In this chapter, we focus on modern understanding of the various phenomena that are classified as SCC and their practical significance.

### 2.09.2 Metal–Environment Combinations Showing SCC; the Issue of Mechanical Difficulty

The major difference between different SCC phenomena is the severity of the mechanical conditions

that are required (e.g., value of stress normalized to the yield stress or necessity of time variation in stress). Such considerations, and the notion of a spectrum of phenomena from SCC through corrosion fatigue, depending on the importance of dynamic straining, were introduced in **Chapter 2.08, Environmentally Assisted Cracking Overview**.

**Table 1** gives a summary of the known SCC systems with one new feature – we try to categorize them according to the difficulty of cracking in a real component, on a scale of 1–5. So, 1 means SCC that requires only a low and not particularly dynamic tensile stress, while 5 means SCC that has only been observed under laboratory conditions and requires dynamic tensile loading (slow strain rate testing), or major cyclic loading, or alternatively an improbably oxidizing potential. Of course, there is always a first time for a phenomenon to occur in the field, but at least we can be sure that a 4 or a 5 would require unusually severe conditions, and might be classified as corrosion fatigue in any case.

An explosion in the number of known SCC combinations (material ... metallurgical condition ... environment) occurred when the slow strain rate test (SSRT) was introduced in the 1970s.<sup>7</sup> This test exposes a smooth tensile sample to the environment, often with electrochemical potential control, and the sample is slowly strained to failure at an engineering strain rate of typically  $10^{-7}$ – $10^{-5} \text{ s}^{-1}$ .<sup>8</sup> The use of the SSRT revealed, almost for the first time, SCC processes that had not yet occurred in the field, such as the cracking of pure copper in sodium nitrite solution.<sup>9</sup> Some of these subsequently did occur in the field; others never have. To call the SSRT ‘too severe’ misses the point – it is a tool for predicting and understanding SCC. No one thinks that all SCC observed in SSRT can or will occur under realistic component loading. Sometimes, especially for hydrogen-related SCC, one can rationalize this neatly in terms of when, during a SSRT, cracks initiate and cause the load-extension curve to deviate from that measured in an inert environment – **Figure 2**.

Some cases of SCC are hard to predict and control because the environment that causes cracking is not well-characterized, or exists only transiently. This is the case for nuclear steam generators, where impurities present at parts per billion or trillion in the feedwater (Pb ... S) concentrate on heat-transfer surfaces under deposits<sup>10</sup> – **Figure 3**. Sometimes these cause SCC during operation, but it is increasingly thought that cracking may occur during plant

start-up, or even during plant shut-down, when oxygen is more available. Test methods that incorporate heat transfer into the test specimen are useful for the clarification of such mechanisms.<sup>11</sup>

The more usual test methods for SCC have been very well discussed by Sedriks, and are not given their own special section in this chapter; miscellaneous comments on test methods are inserted into

**Table 1** Summary of metal–environment combinations that are susceptible to SCC

the text as appropriate. For completeness, we note that test methods can be roughly classified as follows:

- Type of specimen  
Smooth ... defected (notch ... precrack).
- Severity of loading  
Static (constant load ... constant deflection) ...  
Dynamic (monotonic ... slow cyclic).
- Loading mode  
Tension ... bending ... torsion ... multiaxial.
- Environment exposure  
Simple immersion ... electrochemical control ...  
thin layer/evaporating/heat transfer ... gaseous environment.

## 2.09.3 Role of Metallurgy in SCC

### 2.09.3.1 Summary of Metallurgical Factors in SCC

Not all SCC requires a special metallurgical condition – the transgranular cracking of pure copper in sodium nitrite solution, of pure iron in anhydrous

liquid ammonia or CO–CO<sub>2</sub>–H<sub>2</sub>O, or of pure zirconium in hot fuming nitric acid, is a property of the pure metal lattice. But generally, there is some exacerbating metallurgical factor, such as:

- Unfavorable solid solution composition, allowing selective dissolution of one or more less-noble alloy components (dealloying – see **Chapter 2.05, Dealloying**).
- Presence of grain boundaries, especially those with grain-boundary segregation of solutes or impurities.
- Presence of reactive phases at grain boundaries.
- Presence of solute-depleted regions adjacent to grain boundaries.
- Cold work and hardening in general.
- Features tending to localize strain – dynamic strain ageing, intense deformation bands, dislocation ‘channeling’ in neutron-irradiated materials.

Conversely, metallurgy may mitigate the possibility of SCC, as in duplex stainless steels, where the different electrochemical properties of the ferrite and austenite phases dictate different potential dependences of SCC

**Figure 2** Schematic stress–strain curves obtained on carbon steel using the slow strain rate test: in air, in an environment causing severe SCC (e.g., anhydrous ammonia–methanol – see micrograph, courtesy W. Zheng), in an environment where cracking requires severe straining of the sample, to the point that necking has begun before cracks appear (e.g., aqueous  $\text{CO}_2$  solution).

for each phase – and since the alloy can only have one corrosion potential, this is not (usually) a value where both phases can crack rapidly – [Figure 4](#). This topic was discussed in some detail in another review,<sup>12</sup> so will not be elaborated here. Instead, we focus on a more recent development of SCC mitigation by so-called grain boundary engineering.

### 2.09.3.2 Solid Solution Composition

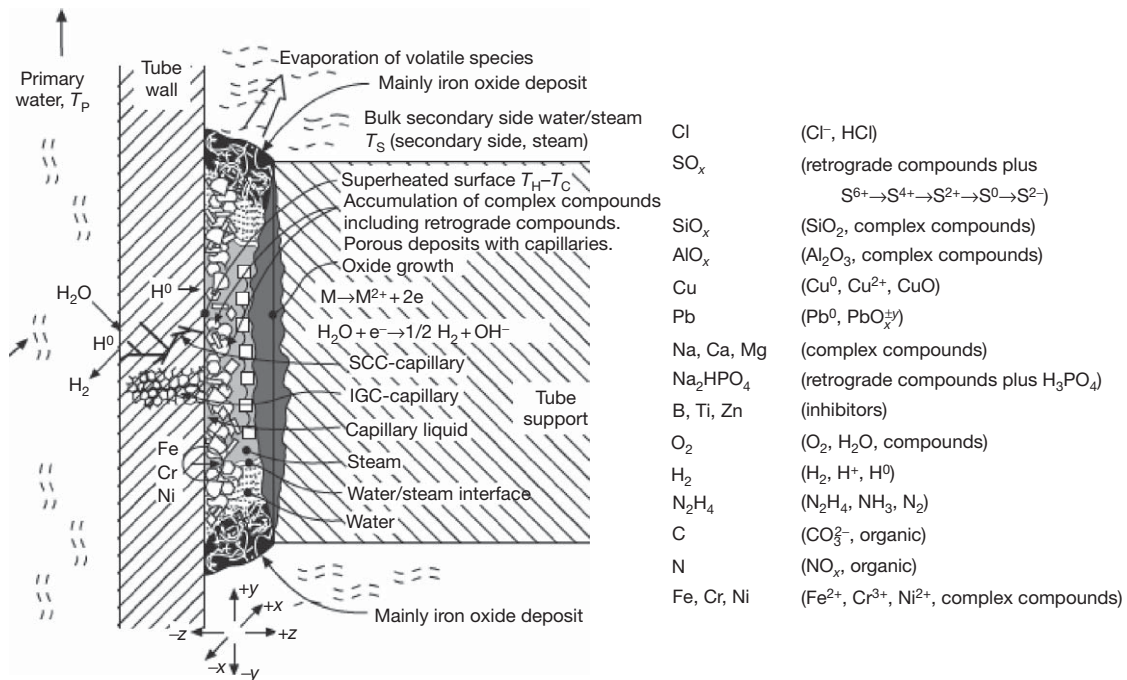

There is persuasive evidence that SCC of many solid-solution alloys involves dealloying (see [Chapter 2.05, Dealloying](#)). In the 1950s, H.R. Copson produced his famous ‘Copson curve’ for time to failure as a function

of nickel content in chloride-induced SCC (Cl-SCC) of austenitic stainless steels, or duplex at the lowest Ni contents.<sup>13</sup> Around the same time, L. Graf produced very similar composition dependences for noble-metal alloys (CuAu, AgAu) where gold played (on a dealloying hypothesis) the same role as nickel.<sup>14</sup> SCC vanishes near the parting limit for dealloying, which is  $\sim 45$  at.% of more-noble metal. The similarity was noticed by Latanision and Staehle,<sup>15</sup> who proposed that nickel was enriched on the crack walls and protected them in lieu of a passive film, along the same lines as Graf (nowadays, we would suggest a more direct causal role of dealloying at the crack tip – see [Section 2.09.10](#)). This very attractive hypothesis was later abandoned, apparently because the new surface analytical technique of Auger electron spectroscopy failed to detect nickel enrichment on fracture surfaces (Staehle, private communication). In fact, there is nickel enrichment, but it is subtle, and there is simultaneous dissolution of the alloy components.<sup>16</sup> Importantly, the state of the crack walls in Cl-SCC is precisely that of active crevice corrosion, so one need not be distracted by considerations of passive films.<sup>17</sup> There is some evidence, from cross-sectional TEM examination, for dealloying at the crack tip.<sup>18</sup>

The Copson and Graf curves are compared in [Figure 5](#), adapted from Newman.

In strong, hot caustic solutions, dealloying of stainless steel is much more blatant than in chloride.<sup>19</sup> A dealloyed layer formed in a caustic environment that induces SCC is shown in [Figure 6](#). Also, the dependence of caustic SCC on nickel content is similar to that of Cl-SCC – for example, SCC occurs readily in type 310 stainless steel (20% Ni), but requires more extreme conditions in Alloy 800 (33% Ni) – but when it does occur, it is spectacular – see [Figure 2b](#) in [Chapter 2.08, Environmentally Assisted Cracking Overview](#). The dealloying of 310SS and its ability to inject a crack into the ductile substrate are shown in [Figure 7](#).

Latanision and Staehle<sup>15</sup> noted that only a small Ni content, ca. 1%, was required for SCC, and at first sight this seems to favor the Graf type of mechanism, rather than one requiring an actual dealloyed layer of definable mechanical properties. But alloys with low contents of more-noble metal can form discrete, nanoporous dealloyed layers at low dealloying overpotentials, because the layer is not pure more-noble metal – it is an alloy. This was clearly shown in [Figure 6](#).<sup>19</sup> Type 316 stainless steel (12% Ni) formed a dealloyed layer with about equal amounts of Ni and residual Fe. [Figure 8](#) shows a better example of

**Figure 3** Complex chemistry of a nuclear steam generator and location of corrosion phenomena. Adapted from Staehle, R. W.; Gorman, J. A. *Corrosion* **2003**, 59, 931–994; 60, 5–63; **2004**, 60, 115–180.

**Figure 4** Reason for the greater resistance of duplex than austenitic stainless steel to chloride-induced SCC – both phases cannot (usually) be at their optimal cracking potential simultaneously, and under mild conditions, there can only be one mixed potential ( $E_m$ ), and one phase is commonly below the minimum possible value of its repassivation potential ( $E_R$ ) by Tsujikawa's criterion. The case illustrated would give very restrained SCC because the  $\gamma$  phase does not crack at all. Reproduced from Newman, R. C. *Stress Corrosion Cracking Mechanisms*. In *Corrosion Mechanisms in Theory and Practice*, 2nd ed; Marcus, P., Oudar, J., Eds.; Marcel Dekker: New York, 2002; pp 399–450.

95Ag–5Au (at.%) alloy. So, one cannot rule out a causal role of an actual dealloyed layer, even at 1% of noble metal, despite assertions to the contrary that appear now and again in the literature.<sup>20,21</sup>

As mentioned in **Chapter 2.05, Dealloying**, not all binary alloy systems show the parting limit (55 at.% less-noble element) seen in binary gold alloys – SCC and superficial dealloying of CuZn or CuAl alloy monocrystals in cuprous ammonia solutions starts at 20 at.% less-noble element, or even a little lower for the CuAl system – **Figure 9**. This has been identified as being at, or close to, a site percolation threshold for the fcc lattice.<sup>22</sup> Departures from this threshold could be due to like-with-like atomic clustering in the solid solution. Intergranular SCC in ordinary polycrystals persists at lower Zn contents, but transgranular SCC vanishes.<sup>23</sup> Evidently, the intergranular variant does not require an actual dealloyed layer, which is reasonable, as pure copper also shows intergranular SCC in ammonia solutions.

Other alloy systems where dealloying should be considered as a cause of, or contributing factor to, SCC include Monel (70Ni–30Cu)<sup>24</sup> and cupronickel. It is likely, though unproven, that some systems may switch from the '55%' to the '20%' threshold at high temperatures such as 300 °C. As a topical example, there is some evidence that Alloy 690 (Ni–29Cr–8Fe) shows dealloying in hot caustic environments, despite the sum of the Cr and Fe contents being well below 55%.<sup>25</sup>

**Figure 5** (a) The 'Copson curve'<sup>13</sup> for chloride-induced SCC of stainless steels; (b) the corresponding behavior of noble metal alloys in aqua regia, Reproduced from Newman, R. C. *Stress Corrosion Cracking Mechanisms*. In *Corrosion Mechanisms in Theory and Practice*, 2nd ed; Marcus, P., Oudar, J., Eds.; Marcel Dekker: New York, 2002; pp 399–450.

### 2.09.3.3 Grain Boundaries, without Precipitation

Since the advent of modern analytical TEM and sample preparation techniques such as focused ion beam (FIB), few have gone back to the classical SCC systems and questioned what is at the grain boundaries, and whether SCC is dependent on a second phase at the boundary, or on some more subtle chemical effect such as equilibrium segregation of alloying elements or impurities. Regarding the case of carbon steel in hot caustic or nitrate solutions, it has been known from the time of H.H. Uhlig<sup>26</sup> that SCC does not occur, or anyway is much more difficult, in 'pure' iron. But it is not clear whether carbide precipitation, or merely monolayer segregation of carbon or some element, is required for SCC. Modern techniques, including atom-probe field ion microscopy provide

some answers, but also raise questions.<sup>27</sup> Most likely, in the case of carbon as the only impurity, fine carbides are required, but we do know that phosphorus and even molybdenum can induce SCC by pure segregation, without carbides (although carbides make matters worse).<sup>28</sup> In a related study, it was shown that an amorphous Fe–P alloy, simulating the grain boundary composition of a segregated alloy, showed enhanced anodic activity in the right potential range to explain the SCC observations.<sup>29</sup> This research was inspired by a classic study on steam-turbine rotor steel by J. F. Newman.<sup>30</sup>

The literature on grain boundary segregation and SCC has become quite large. For example, sulfur is a strong grain boundary segregant in nickel, and causes intergranular corrosion and/or SCC, depending on the conditions.<sup>31</sup> Magnesium segregation has been

**Figure 6** Secondary electron image and matching line profile across a 316SS foil exposed to 50% NaOH at 140 °C for 20 h, and SCC occurring in the same condition. Reproduced from Deakin, J.; Dong, Z.; Lynch, B.; Newman, R. C. *Corros. Sci.* **2004**, 46, 2117–2133.

implicated in SCC of Al–Mg and Al–Mg–Zn alloys.<sup>32</sup> But it would not be sensible to conclude that all intergranular cracking (in the absence of precipitation) is caused by segregation. For example, there is no evidence that this is the case in solid-solution alloys like brass (in aqueous ammonia) or AuCu, AuAg, etc. – in these dealloying systems, it is more likely that the dealloyed layer is simply weaker at the grain boundary – not surprisingly, because it is known that in dealloying, individual grains retain their gross orientation, so a grain boundary is an awkward site for the nanoporosity-formation process to negotiate, leaving inevitable weakness (lack of connection of nano-ligaments across the grain boundary)<sup>33</sup> – **Figure 10**.

Once we consider temperatures in the 300–330 °C range, as in nuclear power plants, intergranular SCC

may start to merge with low-temperature creep fracture, and clean boundaries may actually be more susceptible than those with precipitation. Hydrogen from corrosion may be facilitating such fractures. Arioka *et al.*<sup>34</sup> claimed common evidence for creep-like phenomena including cavities and grain-boundary nickel enrichment in tests of types 304 and 316 steels in both air (at 450–550 °C) and simulated pressurized water reactor (PWR) water (at 360 °C). We await conclusive evidence on the latter, but this is potentially a very important advance. Recently, the same group has argued that intergranular SCC of carbon steel can occur by a hydrogen-assisted creep-like mechanism near reactor operating temperatures,<sup>35</sup> a phenomenon of interest to operators of Canadian CANDU plants, which have carbon-steel feeder pipes. It has also been shown that creep

occurs in Alloy 600 (Ni–16Cr–9Fe) at 360 °C and can be enhanced by hydrogen absorbed from the environment,<sup>36</sup> although a definite role of such creep in SCC has not been established. Again, carbide precipitation at grain boundaries is beneficial. Ingress of oxygen into grain boundaries is probably the key factor in this case, and is discussed later.

Under neutron irradiation at water reactor operating temperatures, stainless steels and nickel base alloys become harder owing to atom displacement and the formation of dislocation loops, and eventually, can suffer from irradiation-assisted SCC (IASCC).<sup>37</sup> Not only the increased hardness, but also

**Figure 7** Dealloying of type 310 stainless steel in 50% NaOH at 280 °C with hydrogen overpressure, showing possible crack injection into the unattacked substrate upon subsequent bending in air. Courtesy of Z.L. Coull, University of Toronto.

radiation-induced segregation (RIS) of alloying elements might contribute to the increased susceptibility to SCC. Vacancies created by irradiation migrate to grain boundaries, and the atomic mobilities are such that Ni is enriched and Cr depleted near these boundaries.<sup>38</sup> This is distinct from ordinary equilibrium segregation and is much wider than a single monolayer. Such phenomena are conveniently studied using proton irradiation, which induces less radioactivity than neutrons, and enables SCC testing to be done in an ordinary laboratory with comparable material properties to neutron-irradiated material.<sup>39</sup> Using such methods, it was shown that light annealing removed some small defects and suppressed SCC without changing significantly the hardness or the RIS.<sup>40</sup> The likely reason is that the small defects were promoting intense strain localization at grain boundaries by a process called dislocation channeling, and suggests that this – not segregation or hardness *per se* – was the primary cause of SCC.<sup>41</sup> Nevertheless, by adding oversized solutes such as Zr, RIS could be reduced, and this did reduce the susceptibility to SCC.<sup>42</sup>

The strain localization induced by neutron irradiation is the most extreme example of a general principle that SCC is more likely – and will occur under milder loading conditions – the more localized is the deformation at the crack tip. This can be illustrated as shown in [Figure 11](#).

#### 2.09.3.4 Grain Boundary Precipitation

The most notorious example of SCC due to grain boundary precipitation is that of weld-sensitized

**Figure 8** Dealloyed layer formed on an unstressed 95Ag–5Au (a/o) alloy in 0.77 M HClO<sub>4</sub> at 20 °C. The layer was grown by applying an anodic current density of 5 mA cm<sup>−2</sup> for 300 s. We can see that a well-defined nanoporous metal layer is formed, even at this low Au content, and obviously must have a very high residual Ag content. The propensity of dealloying to induce tensile stress by lattice shrinkage is also evident – this is part of the reason why alloys crack under such mild mechanical conditions compared with pure metals. Courtesy of N.A. Senior, PhD thesis, University of Manchester, 2004.

**Figure 9** SCC and dealloying of Cu–Zn and Cu–Al monocrystals in cuprous ammonia solution as a function of solute content. Reproduced from Newman, R. C. *Stress Corrosion Cracking Mechanisms*. In *Corrosion Mechanisms in Theory and Practice*, 2nd ed; Marcus, P., Oudar, J., Eds.; Marcel Dekker: New York, 2002; pp 399–450.

austenitic stainless steel (type 304SS) in slightly oxidizing hot water in boiling water reactor (BWR) nuclear power plants.<sup>43,44</sup> The cost of this cracking to the industry, in terms of plant availability, was massive through the 1970s and 1980s (it is interesting to recall that even this cracking was not detected in the laboratory until the introduction of slow strain rate testing). Chromium depletion adjacent to the grain boundary carbides (generally  $\text{Cr}_{23}\text{C}_6$ ) localizes corrosion and causes the cracking. This topic has probably been studied ‘to death,’ and cracking is well under control in those plants that still have 304SS – hydrogen is added to the water in stoichiometric excess compared with oxygen (and other oxidants produced by radiation, principally hydrogen peroxide), and noble metals are plated out on the plant surfaces to catalyze the hydrogen oxidation half-reaction and, thus, ensure that the conditions remain net-reducing.<sup>45</sup>

Although sensitized stainless steel is rather ‘old hat,’ and scarcely exists in modern plants that use low-carbon or stabilized austenitic steels, new insights are still being produced in studies that use low-temperature SCC of sensitized material as a model system to explore fundamental geometric features of SCC.<sup>46</sup> This kind of SCC, which generally occurs in solutions of partially reduced sulfur species (between sulfate and sulfide in oxidation state), is easy to study and amenable to incorporation into advanced tools such as synchrotron light sources. Originally, it was called ‘polythionic acid SCC’<sup>47</sup> because such acids (chiefly tetrathionic acid,  $\text{H}_2\text{S}_4\text{O}_6$ ) were believed to be produced in refinery

equipment by the reaction of iron sulfide scales with oxygen and water. Later both 304SS<sup>48</sup> and Alloy 600 (Ni–16Cr–9Fe)<sup>49,50</sup> were shown to be susceptible to SCC in dilute, aerated thiosulfate ( $\text{S}_2\text{O}_3^{2-}$ ) solutions. Thiosulfate was also the only soluble aggressive species detected in one study of the reaction of FeS with aerated water.<sup>51</sup>

Apart from sensitized stainless steels, the main materials where grain-boundary precipitation is implicated in SCC are aluminum alloys, and especially those of high strength (2000 series, 7000 series, 8000 (Al–Li) series) used in aircraft. SCC can occur in lower-strength 5000 series (Al–Mg–X) alloys<sup>52</sup> when reactive precipitates are present at grain boundaries, such as  $\text{Al}_3\text{Mg}_2$ , the  $\beta$  phase in the binary Al–Mg system, and in other conditions when the stresses are severe. So this is different from SCC of sensitized stainless steel, where it is the solute-depleted zone, not the particle, that is sensitive to corrosion. At the other extreme is the SCC of binary Al–Cu alloys aged to produce Cu-depleted zones adjacent to grain boundaries,<sup>53</sup> where the Cu-depleted material dissolves faster, at a given potential, than the matrix (there are doubts as to whether this should really be called SCC, as nearly all grain boundaries are attacked – it is more like a strain-accelerated intergranular corrosion). Regarding the highest-strength Al–Zn–Mg–Cu (7000 series) alloys, the roles of reactive particles and solute-depleted zones have been controversial, but it appears – currently – that the reactive  $\text{MgZn}_2$  particles are implicated. Such an explanation provides a neat rationalization of the protective effect against SCC of overaging such alloys, as is done for all aircraft construction (the so-called T7 temper). More copper enters the precipitates with overaging, and reduces their excess reactivity compared with the matrix<sup>54</sup> – **Figure 12**.

Recently discovered examples of precipitation effects include the presence of boron, presumably as nickel boride, at the grain boundaries of Monel 400, leading to intergranular corrosion and SCC.<sup>55</sup> However, it is doubtful that such precipitates are necessary in the general case of intergranular corrosion of Monel<sup>24</sup> – they merely accelerate it by providing a nickel-rich path.

### 2.09.3.5 Yield Strength, Including Cold Work Effects

Most SCC is exacerbated by high yield strength, and there must be more than one reason for this behavior – perhaps four or five – depending on the alloy

**Figure 10** Spontaneous intergranular fracture of dealloyed AuAg, and the explanation in terms of limited connection of nano-ligaments across grain boundaries. Reproduced from Senior, N. A.; Newman, R. C. *Nanotechnology* **2006**, *17*, 2311–2316.

**Figure 11** Enhancement of intergranular SCC by strong shear band intersection with grain boundaries, as seen in cold worked and especially neutron-irradiated austenitic steels. Adapted from Was, G. S. Proceedings of the 11th International Conference on Environmental Degradation of Materials in Nuclear Power Systems – Water Reactors, American Nuclear Society, La Grange Park, IL, 2004; pp 965–985.

Zn	2.5	0.8	12
Cu	0.9	0.4	3.3

**Table 4**

Composition of AA7150-T7 constituents measured by analytical TEM (five replicate measurements were made on a single sample)

Element	Matrix	SDZ	Precipitate
Al	94.5	96	52
Mg	3.1	2.6	17
Zn	1.3	0.8	1.5
Cu	1.1	0.3	30

**Figure 12** Demonstration that the reduced anodic activity and (probably) SCC susceptibility of grain boundaries in overaged high-strength aluminum alloy 7150 is due to more copper entering the  $Mg_2Zn$  precipitates. Reproduced from Ramgopal, T.; Gouma, P. I.; Frankel, G. S. *Corrosion* **2002**, 58, 687–697.

system. However, we can make certain generalizations. In very strong steels, exposed to ambient-temperature water (with or without salts), there is no doubt whatever that SCC is due to absorbed hydrogen. The crack path is commonly intergranular, along prior austenite grain boundaries, in tempered-martensite microstructures, but can also be transgranular, cleavage-like in these and in other, more exotic steels such as precipitation strengthened alloys.<sup>56</sup> If we add hydrogen sulfide to the environment, as in sour gas systems, lower-strength steels become susceptible, although ordinary carbon steel remains essentially immune to SCC (it may suffer from hydrogen pressure-induced cracking – see **Chapter 2.08**,

**Environmentally Assisted Cracking Overview**). A theme in recent oil-and-gas material development has been the gradual (very gradual) increase in the yield strength of low-alloy steel that can be employed in sour-gas applications.<sup>57</sup> Stainless steels based on Fe–13Cr (–Ni...–Mo...) have also been developed for mildly sour systems.

There is a class of SCC problem in carbon steels that involves apparently innocuous near-neutral-pH water, yet occurs with alarming frequency on the external surfaces of high-pressure gas transmission pipelines.<sup>58–60</sup> Usually the problem can be traced to some dynamic loading, such as freezing and thawing, and it is thought that SCC cannot occur under perfectly static loading, consistent with a hydrogen effect in low-strength steel, but stronger steels than the usual X-65 grade, such as X-80, seem not to require this ‘fatigue’ component; if such steels are installed in the field, the risk of SCC may be increased (but there is much we still do not understand about this phenomenon).

Since we know that  $H_2S$  increases the percentage of discharged hydrogen that enters the steel, its special severity clearly reflects a correlation between SCC and the concentration of atomic hydrogen that develops at some special site near the crack tip. Exactly what this site is, and what the hydrogen does when it gets there, are still under debate, but the general correlation is secure; we give a recent example of such reasoning.<sup>61</sup> *Ab initio* quantum-chemistry modeling is starting to illuminate some old questions such as – how does hydrogen interact with dislocations?<sup>62</sup> The current view seems to be that hydrogen can either promote or hinder dislocation motion, depending on factors such as strain rate and presence of other interstitials, as well as the crystal structure of the material, presence of interfaces, etc. Spectacular studies of hydrogen-dislocation interactions have been done using *in situ* transmission electron microscopy.<sup>63</sup> Also the growing interest in metals as storage media in hydrogen technology has provided complementary information.<sup>64</sup>

To quantify the SCC of high-strength steels, fracture mechanics techniques are indispensable. Generally speaking,  $K_{Ic}$  falls gradually with increasing yield strength, while  $K_{Isc}$  falls steeply above a certain yield strength value – **Figure 13**.

High-strength steel wire (prestressing steel) is more resistant to SCC than other material forms because it has a highly elongated grain structure, and an intergranular crack has to take a tortuous path to cross the wire.<sup>65</sup> However, failures have occurred in such

**Figure 13** Classical dependence of fracture toughness ( $K_{Ic}$ ) and SCC threshold in seawater ( $K_{Isc}$ ) on yield strength, for old-fashioned ultra-high strength AISI 4340 steel. Reproduced from Newman, R. C. *Stress Corrosion Cracking Mechanisms*. In *Corrosion Mechanisms in Theory and Practice*, 2nd ed; Marcus, P., Oudar, J., Eds.; Marcel Dekker: New York, 2002; pp 399–450.

material. A similar effect protects sheet made from high-strength 2000-series (Al–Cu) alloys.

The effects of yield strength on SCC become murky when we depart from high-strength steels. For aluminum alloys, maximum sensitivity to SCC is commonly seen in the underaged or peak-aged condition, and the beneficial effect of overaging (in the most sensitive AlZnMgCu systems) is thought to involve alloying of Cu into the  $MgZn_2$  precipitates at the grain boundaries. So, the root cause of the beneficial effect is related to the corrosion resistance – that is, anodic kinetics – of the grain-boundary phase, but hydrogen may be the actual cracking agent. Often *preexposure embrittlement* is observed – the material will crack in air or an inert environment after precorrosion<sup>66</sup> – **Figure 14**. Usually this is due to hydrogen, but a further complication is that cracking can even occur without water exposure (especially at slightly elevated temperature) by a creep-like mechanism<sup>67</sup> which sometimes involves a solid-metal-embrittlement type of action of internal lead particles.<sup>68</sup> Generally speaking, in these materials, the effect of yield strength is subordinate to microstructural considerations.<sup>69</sup> A similar picture presents itself when we consider  $\beta$ -titanium (bcc-titanium) alloys<sup>70–72</sup> – there is no doubt that hydrogen can embrittle the material, but the corrosion reaction has to be considered as well and the effect of yield strength *per se* cannot be divorced from microstructure. Incidentally, the SCC of titanium alloys has an exciting history – in the 1960s and early 1970s a high-strength  $\alpha$ – $\beta$  alloy was under consideration for the US supersonic passenger airliner project,

**Figure 14** The preexposure embrittlement phenomenon in AlZnMg alloys. Reproduced from Scamans, G. M.; Alani, R.; Swann, P. R. *Corros. Sci.* **1976**, *16*, 443–459.

but the project was abandoned – partly because of an energy crisis, and partly because of unanticipated SCC of the alloy when precracked.<sup>73</sup> The Apollo program was also plagued by SCC incidents, one involving methanol, which was one of a number of exotic environments found to cause SCC during that period.<sup>74</sup> The history of SCC from 1965 to 1990, including such practical experience, was reviewed by Procter and Newman.<sup>75</sup>

Solid-solution alloys that are not known to be susceptible to hydrogen also show deleterious effects of higher yield strength, and in particular cold work, on SCC. This is highly topical in the nuclear power industry, not only because certain components are inherently coldworked during manufacture (e.g., steam-generator tubes are straightened) but also because surface damage and surface condition generally are known to influence, critically, the initiation of SCC. So, whereas early failures of 304SS piping in BWR systems were confined to weld-sensitized material, nonsensitized but coldworked material began to show failures later on; such cracking will even occur in reducing conditions with hydrogen overpressure,<sup>76</sup> where it is associated with intense strain localization at grain boundaries as revealed by cross-sectional TEM.<sup>77</sup> Such localization, which we discussed earlier in the context of neutron irradiation, is probably fundamental to SCC and to the effect of yield strength, so we may formulate a rule along the following lines – *other things being equal, SCC will occur under milder loading conditions, the more localized is the plasticity near the crack tip*.

Using advanced nanoscale analytical techniques, it has been shown (Lozano Perez, unpublished) that

cold worked austenitic stainless steel exposed to PWR primary water undergoes a kind of internal grain boundary Cr oxidation and elemental Ni enrichment quite similar to what occurs in Alloy 600 in the annealed condition. Apparently the shear bands or twin deformation bands intersecting the grain boundary enhance oxidation along the grain boundary as well as along themselves. So, one could speculate that cold work removes the Fe-induced barrier to internal oxidation of Cr, unifying the mechanism of low-potential SCC in the Ni- and Fe-rich materials.

It should be mentioned that there is a related but different interpretation of the effect of cold work, or of yield strength generally<sup>76,78</sup> – this can only be understood by referring to details of the slip-dissolution model (SDM) for SCC, so we defer the discussion to that section.

Reverting to higher-strength steels for a moment, a problematic phenomenon in power generation is the SCC of turbine components made of quenched and tempered low-alloy steels. This does occur more easily in stronger material, but does not seem to be a hydrogen effect, and occurs at elevated temperatures where hydrogen does not affect the properties of steel because it cannot be localized for long enough near the crack tip.<sup>79</sup>

#### **2.09.4 Crack Nucleation, Crack Coalescence, 3D Crack Morphology, Effect of Distributed Grain Boundary Character**

It is fundamental to SCC that multiple cracks, or at least branched cracks, always occur. Whenever that happens, the nearby crack segments mutually shield each other from the local stress, so that we can say each crack has an effective  $K_I$  value that is less than the nominal one. An important stage in the life of a crack is the point where it becomes connected along the free surface for a distance similar to the specimen or component thickness. This process of crack coalescence was studied by Parkins using mainly intergranular carbonate–bicarbonate SCC of steel<sup>80,81</sup> – **Figure 15** – and is also of key importance in the other type of external pipeline cracking – so-called ‘near-neutral pH,’ transgranular SCC<sup>82</sup> – **Figure 16**. Akashi and others have created detailed conceptual models, suitable for statistical treatment, in which there is a long delay in the formation of a free-running crack<sup>83</sup> – **Figure 17**.

**Figure 15** Coalescence of SCC on a surface (increasing time from top to bottom). Adapted from Parkins, R. N.; Singh, P. M. *Corrosion* **1990**, *46*, 485–499.

The crack coalescence phenomenon does not in itself imply anything distributed about the grain boundary properties – simply that only so many cracks per unit area can nucleate and grow for any distance. But recently the idea of grain boundary engineering has become a popular way to try to suppress, or at least understand, the progress of SCC in industrial alloys.<sup>46,84–87</sup> The development of software for automatic indexing of backscattered electron diffraction (EBSD) patterns was the key technical advance that made this possible. Recently this has been combined with 3D tomographic X-ray imaging in a synchrotron light source – **Figures 18 and 19**. The idea of grain boundary engineering is to create as many ‘special’ grain boundaries as possible within the microstructure by thermomechanical treatment. Annealing twins have special boundaries, but do not in themselves obstruct crack growth to any great extent; the crack easily bypasses the long boundaries. The boundaries that are most important are those that have a particular periodicity of registry between the lattices on either side, not only twin boundaries but also those of higher-order periodicity.<sup>88</sup> Such boundaries are less likely to have segregation of impurities, or detrimental forms of precipitation, and form ductile bridges that are believed – in one theory<sup>46</sup> – to shield the crack tip from part of the applied nominal stress intensity. Under sensitization treatment, they have delayed chromium carbide precipitation. Ordinary industrial alloys already contain special grain boundaries, often in highly variable fractions, and the challenge is to

**Figure 16** Behavior of crack colonies on a pipeline subject to near-neutral-pH SCC. Reproduced from Chen, W.; King, F.; Vokes, E. *Corrosion* **2002**, 58, 267–275.

**Figure 17** Life history of SCC, according to Akashi and Nakayama. Reproduced from Akashi, M.; Nakayama, G. *Effects of the Environment on the Initiation of Crack Growth*; ASTM STP 1298, Philadelphia, PA, 1997; pp 150–164.

increase this fraction whilst maintaining a reproducible, flexible, and economical processing route. A drawback is sometimes that the thermal treatments required to obtain high fractions of special boundaries have to be done at lower than normal temperature, which carries certain hazards such as deleterious precipitation reactions.

EBSD is not only able to index a microstructure – it also gives information on plastic strains and their localization.<sup>89</sup> An important result is that ‘special’ grain boundaries are soft – they do not sustain

dislocation pile-ups. This is a further reason why they are resistant to SCC, which is greatly exacerbated by strain localization as we already discussed.

When SCC occurs in a microstructure with distributed grain boundary properties, the crack initially develops a ramified 3D morphology with uncracked ligaments. There are slightly different ways to approach the problem of cracking resistance in such a geometry. The simplest approach is based on percolation theory<sup>90</sup>; under slow strain rate conditions, where ductile ligaments will always be torn

**Figure 18** Capability of EBSD and tomographic imaging to identify the crack path in 3D for intergranular SCC and identify the boundaries that do, or do not, crack. Reproduced from King, A.; Johnson, G.; Engelberg, D.; Ludwig, W.; Marrow, J. *Science* **2008**, 321, 382–385.

**Figure 19** Appearance of the cracked sample for the kind of experiment shown in [Figure 18](#), and illustration of the presence of ductile ligaments on the fracture surface. Courtesy of D.L. Engelberg.

apart, macroscopic SCC starts to occur when a certain fraction of grain boundary segments are susceptible and can form a connected 3D network (where connection is allowed at edges as well as faces). This percolation threshold is only  $\sim 23\%$ , and such a microstructure would never develop a macroscopic crack under constant load conditions. The same authors noted that for fractions of susceptible boundaries greater than  $89\%$ , no ligaments should form and

SCC should become ‘completely brittle.’ Later the actual grain-boundary Cr contents were taken into account in such an approach.<sup>91</sup> A more sophisticated approach entails restricting the definition of ‘connection’ to grain faces, and incorporating stress via the inability of the crack to propagate in unfavorable directions<sup>84,92</sup> – [Figure 20](#) – but is still essentially a modified percolation concept. In contrast, the model developed in Manchester<sup>93–96</sup> has elements of percolation, but places great emphasis on the shielding effect of uncracked ligaments, by actually calculating the magnitude of such shielding.

Of course, the physics of granular networks can be taken further than this – such networks and their behavior under fracture, dielectric breakdown, etc. have been a favorite topic in statistical physics.<sup>97</sup>

### 2.09.5 Crack Chemistry in SCC

A crack is, literally, a crevice, so we do not need to reiterate concepts that can be found in [Chapter 2.03, Crevice Corrosion](#). Reviews of crack chemistry are available,<sup>98</sup> and a second conference ‘CCPCC2’ was held in 2009 to mark the twenty-fifth anniversary of a landmark conference at the National Physical Laboratory in 1984.<sup>99</sup>

An important aspect of SCC that relates to local chemistry is the evolution of cracks from pits or other localized corrosion sites. There is a mechanics aspect, in that a pit creates a stress concentration, but often the local solution chemistry is the dominant factor. For low-alloy steels, a recent review addressed both the chemistry and mechanics aspects,<sup>100</sup> but the premier example of such a sequence occurs in the chloride-induced SCC (Cl-SCC) of austenitic or duplex stainless steels. This is less well-known than it might be, because much of the published discussion is in obscure sources. [Figure 21](#) shows the early stage of Cl-SCC from a site of crevice corrosion.

**Figure 20** Grain boundary engineering of Alloy 600 against SCC, compared with a model based on connectivity of grain faces (CA – normal; RA – engineered). Reproduced from Lehockey, E. M.; Brennenstuhl, A. M.; Thompson, I. *Corros. Sci.* **2004**, 46, 2383–2404.

Whenever SCC occurs in stainless steel in an aqueous halide environment, the local condition in the crack is similar to that in an active, strongly acidified, but slowly dissolving (because very tight) crevice. This was stated most clearly by Tsujikawa,<sup>18,101</sup> who first argued that the lower critical potential for chloride-induced SCC (CI-SCC) of austenitic stainless steel was simply the repassivation potential (sometimes called protection potential) for crevice corrosion. This immediately replaced fanciful notions such as the critical potential being due to the onset of adsorption of some special species at the crack tip,<sup>102</sup> which are still taken seriously in some textbooks. Given that the propagation rate or velocity ( $v_{\text{corrosion}}$ ) of localized corrosion varies with the geometry and potential because of diffusional or ohmic control of the dissolution rate, we can readily imagine that certain conditions would favor localized corrosion over SCC, or vice versa, even at a given temperature. Then when we factor in temperature, the apparent activation energy that applies to the crack velocity

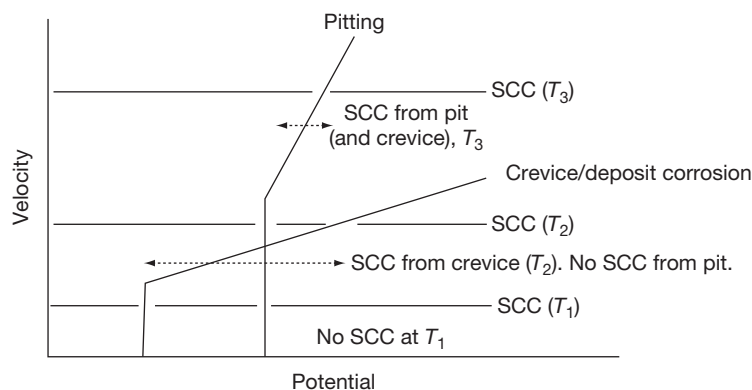

**Figure 21** Early stages of CI-SCC of austenitic stainless steel at low temperature (80 °C), starting from a corroding crevice. Courtesy of S. Wang, PhD thesis, UMIST, 2002.

( $v_{\text{crack}}$ ) is higher than that for  $v_{\text{corrosion}}$ . Obviously, SCC can only occur if  $v_{\text{crack}}(T, \text{alloy}) > v_{\text{corrosion}}(T, \text{alloy}, \text{potential})$  – **Figure 22**.

Such a framework can explain the commonly observed critical temperature for CI-SCC of basic austenitic grades (304[L], 316[L]), as indicated in **Figure 23**. For all but the most extremely slow (i.e., blocked or stifled) localized corrosion, the slowest sustained rates of penetration tend to lie in the range of a few to 10 mm year<sup>-1</sup>. This is also the order of magnitude of  $v_{\text{crack}}$  at 50 or 60 °C. But in order for a crack to initiate from a small pit that is growing at 100 or even 1000 mm year<sup>-1</sup>, the temperature must be much higher, so that the condition  $v_{\text{crack}} > v_{\text{corrosion}}$  is maintained. Thus, when CI-SCC occurs at very high temperatures, it generally initiates from small pits, but at the lowest temperatures, it initiates from underdeposit corrosion sites – or sometimes in tight metal–metal or metal–polymer crevices. SCC of 304SS or 316SS can even be made to occur at room temperature by depositing MgCl<sub>2</sub> (or sea salt, which amounts to the same thing) on the steel, and controlling the relative humidity at a

**Figure 22** Potential dependence of SCC and localized corrosion in austenitic stainless steel, based on the work of Tsujikawa.

**Figure 23** Origin of the 'critical' temperature for Cl-SCC of austenitic or duplex stainless steel, based on the work of Tsujikawa.

value in the 30–35% range where the surface remains wetted by nearly-saturated  $\text{MgCl}_2$  solution.<sup>103,104</sup> Recently authors have rediscovered this kind of effect<sup>105</sup> – and the role of  $\text{MgCl}_2$  (for the sea salt case) has become mildly controversial.<sup>106,107</sup> But the Japanese data from the 1980s were so convincing that there does not appear to be much room for doubt as to the role of Mg. The true application limits of duplex stainless steels are made apparent when such testing is used – a temperature limit of 100–110 °C seems to emerge,<sup>106</sup> contrary to the optimistic assessments made by alloy manufacturers when testing was only being done in NaCl solutions. In further work on this issue, the role of carnotite ( $\text{KMgCl}_3$ ) would repay investigation. It is unlikely that the cases of easy SCC at low temperatures are associated with some Na-rich solution; more likely is that

evaporation experiments done to date have not gone to a high enough level of concentration (80 times at least). But it is also possible that the solids precipitated from seawater have a crevice effect, exacerbating SCC, that is absent when one starts from a binary mixture of NaCl and  $\text{MgCl}_2$ .

Tsujikawa's analysis shows very clearly that the atomistic mechanism of Cl-SCC is not slip-dissolution, but some kind of embrittlement – most likely film-induced cleavage.

The SCC velocity  $v_{\text{crack}}$  is affected strongly by nickel alloying, which lowers  $v_{\text{crack}}$  while leaving  $v_{\text{corrosion}}$  relatively unaffected – thus, as we move from types 304 or 316 stainless steel to type 310 (20% Ni) and eventually Alloy 800 (33% Ni), a higher and higher temperature is required for SCC. Eventually, somewhere above the nickel content of Alloy 800, SCC ceases altogether. This is envisaged – in Toronto anyway – as a parting limit for dealloying (see **Chapter 2.05, Dealloying**).

The situation in aluminum alloys is more complex, because the more susceptible grades are not solid solutions, and some phases are exceptionally reactive ( $\text{Al}_2\text{LiMg}$ ,  $\text{MgZn}_2$ ,  $\text{Mg}_3\text{Al}_2$ ). Even pure water or water vapor can attack such phases,<sup>66</sup> and does so in a peak-aged, high-strength  $\text{AlZnMgCu}$  alloy such as the 7075 grade, although salt water does so more rapidly, and causes more rapid SCC. As mentioned previously, the beneficial effect of overaging on SCC resistance of  $\text{AlZnMgCu}$  alloys is thought to be due to more copper being incorporated into  $\text{MgZn}_2$  precipitates, thus ennobling them. In underaged  $\text{AlCu}$  alloys, localized corrosion attacks Cu-depleted regions adjacent to the grain boundaries

(this is hardly SCC at all, more like intergranular corrosion). So the generalization that SCC is associated with localized corrosion, for passive alloys in halide solutions, remains intact, but has exceptions.

A key question that always arises when considering crack chemistry is – does the crack tip ‘feel’ the externally applied or naturally established electrode potential? Much ink has been spilled on this topic! Clearly, when the crack walls are quite active, it is difficult for the external potential to be thrown down the crack. But for relatively passive systems, such as titanium alloys, external polarization of the crack tip is possible. Importantly, even if there is a large IR potential drop down the crack, and the crack-tip potential is only slightly elevated from its local mixed or corrosion potential, there is a change in crack chemistry in accordance with the diffusion-migration balance for the nonreacting ions such as  $\text{Cl}^-$ . At room temperature, this is one order enrichment of  $\text{Cl}^-$  for every 59 mV ( $2.3RT/F$ ) of potential drop down the crack.<sup>108</sup> For sulfate, it should be one order for every 29.5 mV. This must be a major factor in the SCC of turbine disk steels in dilute condensate.<sup>79</sup> Similarly, crack chemistry also plays a role in the numerous SCC phenomena that occur in high temperature water, especially in the somewhat oxygenated water that is present in a BWR water circuit.<sup>44</sup> If the environment inside the crack were truly pure water, practically no ‘local cell’ action could develop between the inside and outside of the crack, even if oxygen is present outside. In practice, there can be traces of sulfate derived from ion-exchange resin beads, and possibly dissolution of sulfide inclusions in the metal. The crack concentrates these anions by an electromigration process as described above, to the extent that metal cations from the alloy are soluble under the given crack conditions to balance their charge. The electrode potential at the crack tip may be only slightly shifted positive of its open-circuit value, but the open-circuit potential difference between the inside and outside drives the anion accumulation. When oxygen is removed, the potentials inside and outside the crack approach each other and the anion accumulation is less.

A specialized type of crack chemistry consideration occurs in ammonia-SCC of brass.<sup>109</sup> If we immerse a stressed brass sample in dilute – say 1 M – aqueous ammonia in a beaker open to the air, and wait, after a while we see the solution turning blue – this is the cuprammonium II complex ion,  $\text{Cu}(\text{NH}_3)_4^{2+}$ . Shortly after that, the sample starts to crack. The cathodic reaction is the reduction of the

Cu II ammonia complex to the Cu I complex:

which may, depending on the conditions, reprecipitate as a black tarnish film consisting mainly of  $\text{Cu}_2\text{O}$  with some oxidized zinc.

Deep inside the crack, there are no Cu II ions – the crack walls efficiently scavenge these and reduce them to Cu I (so the old notion that adsorption of these ions causes cracking<sup>102</sup> is untenable). The environment at the crack tip is really an ammoniacal Cu I solution (containing zinc), and is very nearly in equilibrium with the copper in the brass. Indeed, SCC occurs in a simulation of such a solution,<sup>110,111</sup> dealloying can be demonstrated electrochemically, and a convincing correlation between such dealloying and SCC was obtained for monocrystals of different zinc contents.<sup>22</sup> Both dealloying and SCC ceased below 20% Zn (intergranular SCC may persist to lower Zn contents) – see **Chapter 2.05, Dealloying**.

## 2.09.6 Role of the Environment in SCC

An important clue to the role of the environment came as soon as fracture mechanics techniques started to be used for SCC investigations: nearly all SCC shows a ‘plateau’ crack velocity at intermediate  $K_I$  values – see **Chapter 2.08, Environmentally Assisted Cracking Overview**. We have to take care that the extent of this region is not exaggerated in studies of ductile alloys,<sup>112</sup> where  $K_I$  becomes invalid because of large-scale yielding at the crack tip, but it is definitely a real phenomenon. So what does that tell us? It tells us that the mechanics are not controlling the crack velocity. So if the rate controlling process is not the mechanics, it must be something ‘chemical.’ The crack velocity could be controlled by:

- The rate of oxidation or dissolution at the crack tip (which in turn can be controlled by the local environment in the crack and the local – not free-surface – potential).
- The rate of hydrogen adsorption or diffusion.
- The rate of some surface diffusion process of metal atoms or ions, and possibly others.

For SCC that occurs in an electrolyte, electrochemical considerations dominate our thinking. There are about six distinct electrochemical circumstances where SCC occurs – **Figure 24**. They are:

**Figure 24** Regions of potential (bold lines) where SCC is likely in given electrochemical circumstances – (A) Active system, near the corrosion potential (strong alloy, hydrogen effect). (B) Active–passive transition. (C) Localized corrosion system near the repassivation potential. (D) Dealloying system near the critical potential. (E) Mild transpassivity. (F) No special reactivity, but high temperature or other exacerbating factor on film growth.

- A more-or-less actively corroding state, where SCC is entirely or predominantly due to hydrogen absorption – for example, high-strength steel in salt water.
- A compromised or borderline passive state, where SCC seems to be due to some anodic process at the crack tip – for example, carbon steel in hot caustic, nitrate, or carbonate–bicarbonate.<sup>113</sup>
- A state of slow localized corrosion (slow because otherwise it would be faster than the cracking) in a halide solution – for example, austenitic stainless steel in hot chloride.<sup>16</sup>
- A state of dealloying (see **Chapter 2.05, Dealloying**) – for example, brass in ammonia solution.<sup>22</sup> This does not exclude a role of dealloying in some of the other categories.
- A state of mild transpassivity, for example, due to Cr VI dissolution in a stainless alloy.
- A stable filmed state, but where the film growth kinetics, especially at deformation features, are such as to allow a certain rate of cracking despite little or no dissolution – for example, cold-worked austenitic stainless steel in hot water.<sup>76</sup>

Also we have to consider various hard-to-classify systems where SCC occurs, but not much seems to happen electrochemically – for example, transgranular cracking of carbon steel in anhydrous liquid ammonia or ammonia–methanol,<sup>114,115</sup> or intergranular cracking of nickel alloy 600 in reducing hot water.<sup>116</sup> These are probably exotic forms of embrittlement, caused by nitrogen<sup>115</sup> and oxygen<sup>117–119</sup> respectively, rather than hydrogen. It was also

suggested, more speculatively, that transgranular SCC of carbon steel in  $\text{CO-CO}_2\text{-H}_2\text{O}$ <sup>120</sup> could be due to carbon embrittlement,<sup>121</sup> and that CO might be involved in SCC of carbon steel in oxygenated alcohols.<sup>122</sup>

Most, though not all, of these SCC schemes can be summarized as follows – SCC may occur, given the right metallurgy and stress, when the metal is passive, but not too passive. Most SCC requires some interaction between the environment and bare metal, and a passive film that forms almost instantaneously screens that interaction. Whether the actual crack growth occurs by purely anodic means, by hydrogen embrittlement, or by some other mechanism, is not always clear; Parkins' concept of the 'stress corrosion spectrum' – hydrogen effects at one end, dissolution at the other, remains valid today.<sup>123,124</sup> As a prelude to the next sections, we show '1980s' and '2000s' SCC spectra in **Figure 25**.

## 2.09.7 Anodic SCC Models

Since the 1940s, a popular scheme for the growth of SCC has been the accumulation of small dissolution or oxidation events at the crack tip, each caused by the rupture of some partially protective surface film – **Figure 26**. A popular term, probably coined by R.W. Staehle, is 'slip-dissolution,' recognizing that not all (or perhaps not any) of the oxidized metal remains actually dissolved in the small volume of solution inside the crack.

In the SDM, the plateau crack velocity is explained by postulating that above a certain  $K_I$  value, the crack tip is essentially bare the whole time, and dissolves or oxidizes at a limiting rate that is set by the local chemistry and potential in the crack. The actual value of the plateau velocity is then given by:

$$v = \frac{i_{\max} \Omega}{nF} \quad [1]$$

where  $v$  is the crack velocity,  $i_{\max}$  the maximum anodic current density flowing on the bare metal surface,  $\Omega$  the molar volume of the metal,  $F$  is Faraday's constant, and  $n$  is the number of electrons transferred per metal atom dissolved or oxidized.

In the 1970s and 1980s, many publications showed agreement of plateau velocities with eqn [1], where  $i_{\max}$  was determined by various transient electrochemical methods, including rapid tensile straining,<sup>125</sup> scratching,<sup>126</sup> potential stepping,<sup>127</sup> or rapid potential scanning.<sup>113</sup> Parkins played a great role in

The 1980s SCC spectrum									
Anodic	CS	Brass	$\gamma$ SS	Al alloy	CS	Ti alloy	Mg alloy	HSS	Hydrogen

Figure 25 Old and new SCC 'spectra.'

Figure 26 The slip-dissolution (or oxidation) model, after Staehle.

evaluating and comparing these techniques in carbon steel systems – Figures 27 and 28. But throughout, there were concerns that the model was being over-stretched beyond carbon steel, with such views emanating especially from specialists in hydrogen embrittlement. Application of the SDM to SCC of Al–Mg alloys was certainly controversial.<sup>128</sup> Currently, it appears that the SDM may be valid for intergranular SCC of carbon steel in caustic, nitrate, or carbonate–bicarbonate solutions, and for a number of stainless alloys in hot water. Transgranular SCC in general does not seem to fit well with the SDM – according to Sieradzki, growth of a sharp transgranular crack is not possible under static loading,<sup>129</sup> and there are kinetic difficulties in many systems, such as

Figure 27 Analysis of current decays after potential stepping from a reducing potential to the given potential, for carbon steel in aqueous carbonate–bicarbonate, showing correlation with SCC velocity ( $I_0$  = peak current;  $I_5$  = current after 5 s). Modified from Parkins, R. N. *Corros. Sci.* **1980**, 20, 147–166.

brass in nitrite solution.<sup>130</sup> In general, it is probably safe to say that the SDM may apply to a number of cases of intergranular SCC in passivating environments without chloride-induced localized corrosion. It certainly does not apply to – say – chloride-induced SCC (Cl-SCC) of austenitic stainless steel, where the condition of the crack walls and tip is precisely that of an actively corroding crevice with a low pH and no possibility of very high local anodic current densities.<sup>16,131</sup> Recent pronouncements to the effect that the SDM does explain Cl-SCC<sup>132</sup> did not take into account the crack chemistry or realistic current densities that could flow at the crack tip when the metal is already in the active state.

**Figure 28** Similar correlation to **Figure 27**, but using the difference between the current densities measured in fast and slow potential scans. Modified from Parkins, R. N. *Corros. Sci.* **1980**, 20, 147–166.

Below the plateau crack velocity, the SDM postulates that partial repassivation of the metal occurs between film rupture events at the crack tip – **Figure 29**. So instead of  $i_{\max}$ , we write  $\bar{i}$  as the mean anodic current density at the crack tip; this is given by:

$$\bar{i} = \frac{1}{\tau} \int_0^{\tau} i(t) dt \quad [2]$$

where  $i(t)$  is the anodic current density transient on the bare metal surface, and  $\tau$  is the interval between film rupture events. The crack velocity is now:

$$v = \frac{\bar{i}\Omega}{nF} = \frac{\Omega}{nF\tau} \int_0^{\tau} i(t) dt \quad [3]$$

If we write the crack-tip strain rate as  $s$  (for the moment we suppose this is applied externally), and the strain

**Figure 29** The variation of anodic current density at the crack tip with time, as envisaged by the slip-dissolution model.

to failure of the oxide film as  $f$ , then  $\tau = f/s$ , and

$$v = \frac{\Omega s}{nFf} \int_0^{f/s} i(t) dt \quad [4]$$

This treatment begs a number of questions, including – is the process really stepwise like this, or can it be considered as a more continuous process of stretching of a partially formed, perhaps gel-like film? Probably it is stepwise locally, but along the crack front at any given moment, there will be elements of surface that are at all possible stages of the cycle.

It is fundamental to the SDM that dynamic plasticity is occurring at the crack tip. Sometimes this is supplied by external means, such as thermal stresses that accumulate during the start-up of a BWR. But what about purely static loading – where does the dynamic strain come from in that case? In part, this can be due to low-temperature creep, but most authors have appealed to the crack growth itself as the source of the dynamic strain. Ahead of a crack, there is a plastic strain distribution  $\varepsilon(r)$  where  $r$  is distance from the crack tip – **Figure 30**. Since  $\varepsilon$  falls off with increasing  $r$ , any corrosion or oxidation process that extends the crack must cause the whole strain distribution to move in the direction of crack growth, and this causes a strain transient ahead of the crack. This scheme was first clearly described by Vermilyea<sup>133</sup> and has been developed recently by Shoji<sup>134</sup> using a more modern strain distribution that had performed well in direct experimental tests on a ferritic material<sup>135</sup> – **Figure 31**. This possible, successful, though much-criticized, form is due to

**Figure 30** Basis for growth of SCC by slip-dissolution under static load – the crack growth itself provides dynamic plastic strain.

**Figure 31** Comparison of experimental plastic strain distributions ahead of a growing crack with two reasonable models (for FeSi monocrystal samples). Reproduced from Gerberich, W. W.; Davidson, D. L.; Kaczorowski, M. J. *Mech. Phys. Solids* **1990**, 38, 87–113.

Gao and Kwang<sup>136</sup> – they gave the strain ahead of the crack tip as:

$$\varepsilon_{ct} = \beta \left( \frac{\sigma_y}{E} \right) \left\{ \ln \left[ \left( \frac{\lambda}{r} \right) \left( \frac{K}{\sigma_y} \right)^2 \right] \right\}^{n/(n-1)} \quad [5]$$

where  $r$  is distance ahead of the crack, and  $n$  is the inverse strain hardening coefficient;  $\beta$  and  $\lambda$  are dimensionless.

Recently this picture has been challenged in some of its details, and its status remains unclear. According to Sieradzki,<sup>129</sup> it can only work if the corrosion is

strongly directional, leading to the idea that it is – perhaps – only valid for intergranular SCC where there is an active path of some kind. M.M. Hall also criticizes the Vermilyea–Andresen–Shoji approach in many respects and has used a modified creep cracking approach to develop a different type of ‘SDM’.<sup>137–139</sup> Generally, Shoji’s variant of the SDM is very attractive and makes a good playing field to explore the dependence of SCC on various parameters, but the last word has not been said on this subject using such continuum approaches.

When we discussed cold work effects in SCC, discussion of the approach taken in the SDM was deferred to this section. Essentially, the SDM proposes that a stronger material has a sharper crack. Now this has become a controversial issue, not least because stress corrosion cracks are much sharper than one would naively expect from the equations of ordinary elastic–plastic fracture mechanics, such as the one that gives the crack-tip opening displacement ( $\delta$ ) as a function of stress intensity factor, modulus, and flow stress:

$$\delta = \frac{K_I^2}{E\sigma_0} \quad [6]$$

which gives values for  $\delta$  on the order of microns rather than the experimentally observed nanometers.<sup>140</sup>

But, allowing the basic assumption of the sharper crack, the SDM postulates, following Vermilyea, that the average dissolution (oxidation) rate at the crack tip (allowing for film rupture and partial repassivation) and the time-averaged plastic strain rate at and ahead of the crack tip mutually cause and determine each other. Some might call this a ‘circular’ argument, but it is not, in principle. So, we develop two equations – one giving the strain transient that results from a particular corrosion transient, and the other being the converse. Solving these simultaneous equations gives the crack velocity as a function of the stress intensity factor  $K_I$ , with one major adjustable parameter – the cutoff distance ahead of the crack tip at which we calculate the plastic strain rate for the purposes of the calculation (the applicable strain distribution does not allow for calculation of the strain or strain rate exactly at the crack tip). Now, we can see that if the material is stronger, and the crack sharper, the corrosion transient at the crack tip does not have to penetrate the material so deeply to create a given strain rate (other things being equal), so when we solve the equations we get a faster crack velocity. The present author developed Shoji’s equations, identified some critical issues, and made

**Figure 32** (a) Graphical depiction of how solutions to the equations of the slip-dissolution model lie at the intersection of two relationships between crack velocity and crack-tip strain rate. The possibility of two crack velocities satisfying the equations for negative loading rate is illustrated. (b) Illustration of how this graphical formulation of the slip-dissolution model leads to the creation of a  $V$ - $K$  curve. Reproduced from Newman, R. C.; Healey, C. *Corros. Sci.* **2007**, 49, 4040–4050.

some new predictions such as the existence of dual steady states under certain loading conditions<sup>141</sup> – [Figure 32](#).

### 2.09.7.1 Interlude – Ultra-Sharp Cracks

Spectacular work has been done on the geometry, micromechanics, and microchemistry of SCC by Bruemmer and Thomas at the Pacific Northwest National Laboratory, which directly addresses this issue of crack sharpness as well as many other microscopic mechanistic issues, including strain localization by shear bands, alloy enrichment and depletion ahead of the crack, oxygen penetration, and porosity development ahead of the crack, as well as issues connected

with neutron irradiation and impurity concentration (Pb...S).

Several figures are reproduced from these authors' recent work with their original captions in [Figures 33–36](#).

### 2.09.8 Chemistry Considerations for SCC by Slip-Dissolution

When unalloyed carbon steel cracks in nitrate, caustic, or carbonate–bicarbonate solution, the conditions are always such as to promote the formation – perhaps fleetingly – of soluble complexes. In caustic solutions, the soluble species is  $\text{Fe}(\text{OH})_4^{2-}$ ; in carbonate–bicarbonate, it is  $\text{Fe}(\text{CO}_3)_2^{2-}$ <sup>142</sup> (or similar bicarbonate complex<sup>143</sup>), and in nitrate it is probably an unknown complex that forms with some reduction product of nitrate. The present author used to believe that nitrate SCC was happening near the active–passive transition, like caustic or carbonate–bicarbonate SCC, but actually, the potentials are very oxidizing, in what could be called a transpassive region<sup>113</sup> – at least when the solution is hot and concentrated. But iron does not normally suffer from transpassive dissolution. What must be happening is that normally, nitrate contacting an iron surface is reduced so far (e.g., to  $\text{N}_2$  or  $\text{NH}_4^+$ ) that it becomes harmless, but that in a certain range of potentials, it is reduced to something that forms a soluble complex with iron. We do not know what that is – it could be an NO species. ‘Transpassive’ corrosion also occurs in zirconium in strong nitric acid, and must be due to a similar complexation effect.<sup>144</sup>

As Parkins has often shown, intergranular SCC of carbon steel is preceded by mild intergranular corrosion, and to the extent that fine carbides are to blame, this can be rationalized by their diminished passivation ability.<sup>145</sup> Similarly, where phosphorus segregation is involved, insights can be obtained by studying an amorphous iron phosphorus alloy<sup>29</sup> or simply an iron phosphide, as a rough simulation of the reacting material at the grain boundary. In the case of sensitized stainless steels or nickel base alloys, a range of alloys with reduced Cr contents can be prepared for transient electrochemical experiments.<sup>126</sup>

### 2.09.9 More Comments on Hydrogen Embrittlement as a Mechanism of SCC

Some of the oldest controversies in SCC research concern the role of hydrogen embrittlement. R.N.

**Figure 33** Crack tip region in CW316LSS sample tested in BWR HWC: (a) TEM brightfield image showing shear bands at tip. (b)  $\langle 111 \rangle$  Relrod darkfield image highlighting faults (one of four variants) in grain at right. (c) Relrod darkfield image highlighting faults along grain boundary in grain at left. Inset diffraction patterns show relrod reflections used for imaging. Commentary – these images show extraordinary martensite-like shear transformations ahead of cracks in cold-worked stainless steel, and vividly illustrate the strain localization that is responsible for much of the severity of SCC in cold worked material. Adapted from Toloczko, M. B.; Andresen, P. L.; Bruemmer, S. M. SCC Crack Growth of Cold-Worked 316LSS in BWR Oxidizing and Hydrogen Water Chemistry Conditions, Proceedings of the 13th International Conference Environmental Degradation of Materials in Nuclear Power Systems – Water Reactors, Canadian Nuclear Society, 2007; Paper 141.

**Figure 34** Open (a) and oxide-filled (b) crack tips in a BWR core shroud sample. EDS x-ray maps of oxide-filled tip (c) show Fe/Ni loss in oxide, Ni concentrated ahead of tip, and Mo segregation along the leading grain boundary. Commentary – this is neutron-irradiated material from plant, so there could be complex processes at play, including atomic mobility that leads to Ni enrichment ahead of the crack, and Mo segregation. Adapted from Thomas, L. E.; Edwards, D. J.; Asano, K.; Ooki, S.; Bruemmer, S. M. Crack-Tip Characteristics in BWR Service Components, Proceedings of the 13th International Conference Environmental Degradation of Materials in Nuclear Power Systems – Water Reactors, Canadian Nuclear Society, 2007; Paper 143.

**Figure 35** TEM underfocus image showing oxide-filled IG crack and adjacent tunnel-like structure along walls in Ringhals-4 alloy 182 sample. Commentary – the striking feature is the apparent oxidation along dislocation lines either side of the crack. Adapted from Thomas, L. E.; Bruemmer, S. M. *High-Resolution Analytical Microscopy of Environmental Cracks in Alloy 182 Weldments*, 11th International Conference on Environmental Degradation of Materials in Nuclear Power Systems – Water Reactors, American Nuclear Society, 2003; p 1212.

Parkins used to refer to a stress corrosion ‘spectrum’ that had SCC of high-strength steel at one end and SCC of ordinary carbon steel at the other, with various aluminum and titanium systems near the middle.<sup>123</sup> Recently titanium alloys seem to have arrived firmly somewhere near the hydrogen (high-strength steel) end,<sup>70</sup> although clearly the discharge of hydrogen ions depends on electrochemical factors like the repassivation rate of the metal at the crack tip. Nowadays, no one seems to believe in Theodore Beck’s ‘electrochemical knife’ (SDM) that he proposed in the 1960s and early 1970s.<sup>146</sup> A general difficulty with aluminum and titanium alloys is that hydrogen is always generated in copious quantities at the crack tip, but this does not mean it always plays an important role in cracking. Probably these mechanisms will continue to be considered somewhat hybrid in nature. A similar comment could be made about martensitic stainless steels in ambient chloride solutions, or carbon steel in near-neutral-pH bicarbonate solutions.<sup>147</sup>

It was once thought that high-strength low-alloy steels immersed in salt water had an acidic crack chemistry, and that this assisted hydrogen discharge in the crack,<sup>148</sup> but later it appeared that this was

mistaken, at least for steels without chromium.<sup>149,150</sup> The original experiments suffered from air-oxidation of Fe (II) to Fe (III), causing acidification. But crack depth also affects the crack chemistry (deep cracks tend to self-corrode and thus have less or no tendency to acidify, even with Cr alloying), and it was sometimes reported in the 1980s that short cracks grew faster than long ones.<sup>151</sup> The pH changes in such short cracks depend very sensitively on the external corrosion potential (which depends on alloying content), and no generality of the ‘chemical short crack effect’ was ever established. Essentially, we know that acidification occurs, with Cr alloying, if we anodically polarize the material from its natural corrosion potential. So under free corrosion conditions, there has to be both Cr alloying and some other element (Mo, Ni for example) that ennobles the anodic reaction on the free surface – then, if we are (un)lucky, we can see the chemical short crack effect. Maraging steels, which contain large amounts of Ni, are good candidates for such behavior.

There is no space here for a detailed discussion of hydrogen embrittlement mechanisms, but the subject has been very well-documented, not only in journal literature but in a series of conferences.<sup>152</sup> To the nonspecialist, theories of hydrogen effects seem very confusing and mutually contradictory – some theories postulate a kind of hardening, leading to decohesion of the lattice or of a grain boundary,<sup>153</sup> while others postulate a local softening leading to highly localized plastic rupture.<sup>154,155</sup> Strain rate affects the predominant mechanism. Quantum mechanics modeling gives insights into the interaction of hydrogen with other solutes,<sup>62</sup> with dislocations, and with grain boundaries. Two types of softening effect are proposed in the literature – Lynch<sup>152</sup> sees this as a surface or very near-surface effect attributed to a lifting of a compressive surface stress by hydrogen adsorption (or very local absorption), while the ‘HELP’ (hydrogen enhanced local plasticity) mechanism<sup>63</sup> postulates that internal hydrogen reduces the repulsion between dislocations in their slip plane – **Figure 37**.

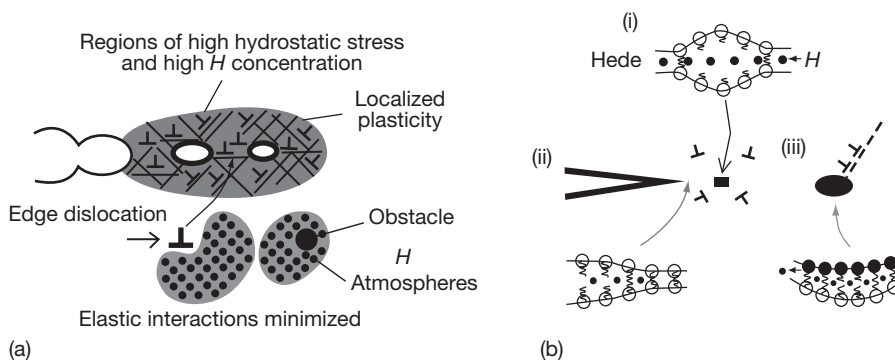

### **2.09.10 Film-Induced Substrate Fracture (‘Film-Induced Cleavage’)**

It is recognized that certain cases of SCC are too rapid to be due to any version of the SDM, and that some of them occur under conditions where hydrogen absorption can be ruled out. Many of these have in common that they occur in relatively concentrated solid

**Figure 36** EDS maps showing the leading edge of IG attack ahead of primary-side IGSCC in an Alloy 600 steam generator tube are presented. Cr is highly enriched in the tip oxide and Ni is enriched along the grain boundary ahead of the tip. Commentary – these depletions and enrichments need to be studied in the context of internal oxidation and other models. Adapted from Bruemmer, S. M.; Thomas, L. E. Crack-Tip Examinations of Primary-Water Stress Corrosion Cracking in Alloy 600, Proceedings of Fontevraud 6 International Symposium on Contributions of Materials Investigations to Improve the Safety and Performance of Light-Water Reactors, French Nuclear Energy Society, 2006; p 603.

**Figure 37** Plastic hydrogen fracture mechanisms, according to Lynch. Reproduced from Lynch, S. P. In *Corrosion/2007*; NACE: Houston, TX, 2007; Paper No 489.

solutions – brass, copper–gold or silver–gold alloys, austenitic stainless steel.<sup>18</sup> A natural idea is that such rapid cracking could be due to dealloying (see **Chapter 2.05, Dealloying**), but not just to a repetitive process of formation and fracture of a dealloyed layer – the rapid cracking requires that the fracture

of the dealloyed layer injects a brittle microcrack, even into a fcc substrate that is normally considered unconditionally immune to brittle fracture<sup>156</sup> – **Figure 38**. The original source for this concept was a remarkable study on brass by Edeleanu and Forty in the late 1950s.<sup>157</sup> Optical microscopy of the side

surface of an  $\alpha$ -brass crystal immersed under stress in ammonia solution showed what appeared to be regular brittle crack jumps of a few microns, each starting and ending at a slip trace. The authors stopped short of stating that the fcc lattice was undergoing a true cleavage process, as this was considered impossible even then. They proposed that the material between slip bands was embrittled by short-range order, and that corrosion – perhaps selective – at the slip band was required to reveal this intrinsic brittleness in the material. Their observations were confirmed by the group of E.N. Pugh.<sup>158</sup> Pugh introduced a clever method to detect discontinuities in crack growth, based on the use of periodic load pulsing to mark the fracture surfaces, and deduced that indeed the cracks were proceeding by a series of jumps. Acoustic emission was used as supporting evidence. Pugh did not adopt the short-range order suggestion, but did consider for some time that hydrogen might be causing the effect; he later rejected this, paving the way for the acceptance of a cleavage process initiated by dealloying.<sup>159</sup> Sieradzki and Newman presented arguments based on dislocation dynamics that went some way toward establishing a feasible framework for such effects.<sup>160,161</sup> This was considered a bizarre suggestion by many, but recent insights into the extraordinary mechanical properties of dealloyed layers (near-theoretical strength in compression,<sup>162</sup> size-scale-dependent elastic modulus,<sup>163</sup> surface stress-driven bending<sup>164</sup>) are reawakening interest in the possibility that such crack injection can occur.<sup>165</sup> Pugh considered that intergranular cracking in brass was a continuous process, but actually the strongest evidence for the film-induced fracture hypothesis comes from studies of intergranular SCC in noble-metal

**Figure 38** The film-induced cleavage concept, for a system showing dealloying.

alloys<sup>166–168</sup> – **Figure 39**. Crack jumps into a silver–gold substrate of 50–100  $\mu\text{m}$  can easily be obtained from preformed dealloyed layers. A key experiment is to dealloy under an applied potential, then step the potential to a value where little or no further

**Figure 39** Brittle fracture of AuAg – intergranular or transgranular – obtained after surface dealloying; the middle picture illustrates the effect of ageing the dealloyed layer, which destroys its ability to inject a brittle crack by coarsening its nanoporosity. Reproduced from Barnes, A.; Senior, N. A.; Newman, R. C. *Metall. Trans. A* **2009**, *40*, 58–68.

faradaic reaction can occur, then load the sample to failure. This also showed good promise for transgranular fracture,<sup>166</sup> although more work remains to be done in that area. In both cases, ageing of the dealloyed layers destroys their ability to inject a crack – probably owing to coarsening of their porosity by surface diffusion.

Clearly, the crack injection phenomenon relies on the special properties of dealloyed layers, including their intrinsic brittleness. A key aspect is the absence of a crystallographic interface – dealloyed layers retain the same lattice orientation that they had before dealloying, so the crack can cross into the substrate without meeting any dislocation structures. Provided it is injected at a velocity close to the velocity of sound in the crystal, it can continue to grow for some distance even in a fcc material, as discussed by Sieradzki and Newman.<sup>158</sup>

### 2.09.11 Surface Mobility, Vacancy Based Models, and Others

A large amount of research has been done by the group of J.R. Galvele, based around a surface mobility model (SMM) that he proposed in 1987.<sup>169</sup> This is a kind of creep crack growth model in which crack extension occurs by surface diffusion of metal atoms (perhaps partially oxidized or chelated – this is not always clear) away from the crack tip. The basic crack growth equation is – using Galvele's own notation:

$$\text{cpr} = \frac{D_s}{L} \left[ \exp\left(\frac{\sigma \cdot a^3}{kT}\right) - 1 \right] \quad [7]$$

where cpr means crack propagation rate,  $D_s$  is the applicable surface (self) diffusivity,  $L$  is a diffusion length along the crack flank (Galvele always uses  $10^{-8}$  m for this),  $\sigma$  is the opening stress at the crack tip, and  $a^3$  is the atomic size (approximate volume of a vacancy). The crack velocity is considered to correlate with the melting point of a surface compound (which in turn correlates with surface diffusivity on a contaminated surface), or in some cases with a kind of enhanced exchange of metal atoms at the crack surface (exchange current), for which a different equation was developed<sup>170</sup>:

$$D_s = \frac{i_0 N_A A n^2 a^4}{6F} \quad [8]$$

where  $i_0$  is the exchange current density,  $N_A$  is Avogadro's number,  $A$  is the atom fraction of base (reactive) metal atoms in the alloy (this was called

$AF$  in the original paper),  $n$  is a kind of dimensionless distance or average hop size,  $a$  is the atom size,  $F$  is Faraday's constant, and the 6 arises because this is the number of neighboring sites of an atom in a close-packed plane.

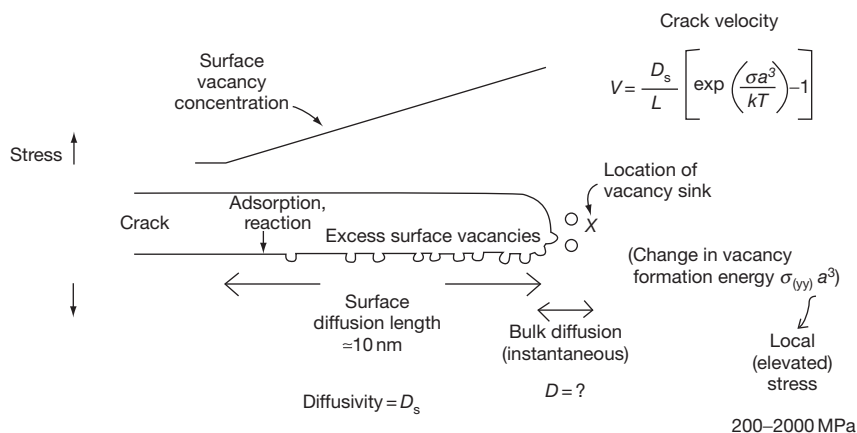

The SMM does have the attractive feature that (with an atomically sharp crack, and allowing for some adjustable parameters such as stress at the crack tip) it seems to rationalize literature data on SCC velocities. Not enough independent research has been done on the concept to give a final answer as to its merits.

The chemical potential gradients could be in the right direction for crack growth in the SMM, but – according to Friedersdorf and Sieradzki<sup>171</sup> – only if one neglects capillary effects – tight cracks would close up, and the SMM can only work with a relatively blunt crack (as in the creep analogues that can be found in the literature). Friedersdorf and Sieradzki also stated that the change in vacancy formation energy due to stress ( $\sigma a^3$ ) had been wrongly assigned because this quantity is appropriate for the interior of the solid, not the crack-tip surface. They also argued that chemical potentials should be used, not concentrations. The crack velocities estimated by Friedersdorf and Sieradzki are many orders of magnitude lower than those suggested by Galvele, although their amended model does have the drawback that it assumes equilibrium vacancy concentrations, as pointed out by Galvele himself.<sup>172</sup>

One source of confusion in the published discussions of the Galvele model is that between 1987 and 1994, he shifted the location of the site where the stress was assumed to act from the crack tip surface to somewhere just ahead of the crack, thus – perhaps – justifying the use of  $\sigma a^3$ . This is an unsatisfactory aspect of the SMM, as it introduces an arbitrary additional vacancy transport process that must occur within the solid – this is simply assumed to be rapid compared with transport along the crack flank. Friedersdorf and Sieradzki were analyzing a version of the SMM that had been changed a few months before they published their analysis, to deal with the  $\sigma a^3$  problem.

Our summary of the current state of the SMM is shown in **Figure 40**.

Intriguing intergranular SCC phenomena were demonstrated by the Galvele group for copper and silver, and silver alloys, in hot, dry halogen atmospheres.<sup>173–175</sup> The lowest temperature where cracking was studied was 200 °C. These observations were considered to be a cornerstone of the SMM, as they related directly to classic studies of enhanced surface

**Figure 40** Current state of the Surface Mobility Model, as envisaged by the author.

mobility due to halogen adsorption.<sup>176</sup> Other explanations are possible, of course. Ion mobility in copper and silver halides could be high.

#### 2.09.11.1 Vacancy Injection Models for Low-Temperature SCC

It is interesting that the moving of the vacancy sink ahead of the crack turns the SMM into a *vacancy injection* model, qualitatively similar to those proposed by other authors, including E.I. Meletis<sup>177</sup> and the late Denny Jones<sup>178</sup> who believed that he had detected interdiffusion in metallic bilayers subjected to anodic dissolution. In those models, the enhancement by stress of equilibrium vacancy concentration inside the solid was not taken into account – at least not explicitly – although it was probably part of the thought process.

One of several ‘orphan’ SCC models is that of Aaltonen and others in Finland, based on internal friction studies<sup>179,180</sup> – **Figure 41**. These results are so surprising (much more so, we would submit, than film-induced cleavage) that no other author has seriously addressed them. Essentially, these authors showed that anodic polarization of copper wires at 80 °C in a sodium nitrite solution, under conditions promoting duplex Cu(I)–Cu(II) oxide formation, produced defects that behaved like vacancies under the standard protocols used for internal friction measurement. They even claimed a reduction in shear modulus of the whole wire specimen. Later they reported an increase in creep rate under similar conditions.<sup>181</sup> One’s immediate reaction is that even if such vacancies were to be produced, they must be confined within nanometers of the metal–film

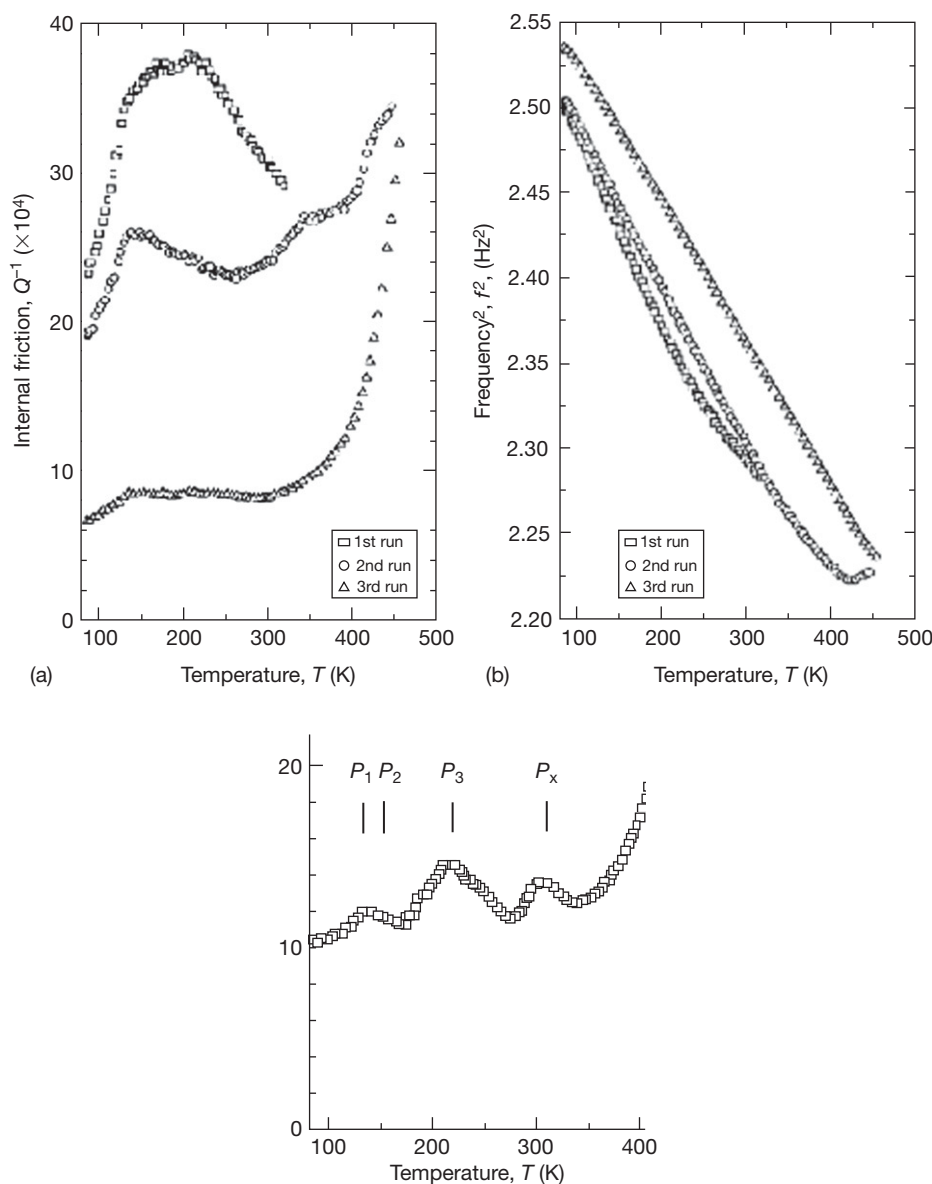

interface, so how is it possible for this nm-thick layer to dominate the internal friction response, or sample modulus, when the smallest sample dimension is 0.5 mm? Yet the results are quite striking, showing Hasiguti peaks in the anodically treated samples. One possibility (acting as devil’s advocate) is that there is an autoreduction or disproportionation of a thick oxide, which produces metallic copper with a high defect density. Yet even in that case, the defected metallic layer should be a tiny fraction of the total sample dimension. But we should certainly not dismiss such observations. Metals like copper and silver may have high mobility for certain substitutional elements.

Very recently (Hanninen *et al.*, unpublished) a variety of techniques have been used to support the proposed vacancy injection model. Dislocation structures are altered near the surface during anodic polarization in the range of potentials that cause SCC of copper in nitrite. This does not mean that vacancies are penetrating the material to the entire depth to which altered behavior is observed – as shown many years ago, a near-surface effect can alter bulk mechanical properties, at least in fairly thin wire or sheet. So the relevance of vacancy injection to crack propagation may lie in the inducement of more intense localized plasticity, rather than some kind of embrittlement by the vacancies themselves.

Of course, vacancies can be involved in creep-like SCC phenomena when the temperature exceeds 300 °C, as discussed earlier.<sup>34</sup>

#### 2.09.11.2 Adsorption-Induced Dislocation Emission

According to Lynch (private communication), ‘surface mobility’ can be harmonized with a mechanism of

**Figure 41** Upper: Temperature dependence of internal friction  $Q^{-1}$  (a) and oscillation frequency  $f^2$  (b) for copper polarised in 0.3 M  $\text{NaNO}_2$  solution for 2 h at  $-150 \text{ mV}_{\text{SCE}}$  and subsequently for 10 h at  $+100 \text{ mV}_{\text{SEC}}$  at 353 K ( $80^\circ\text{C}$ ). During first run heating was performed up to 320 K, and during second and third runs up to 450 K. Lower: Location of the usual Hasiguti peaks for copper. Reproduced from Aaltonen, P.; Jagodzinski, Y.; Tarasenko, A.; Smouk, S.; Hanninen, H. *Corros. Sci.* **1998**, *40*, 903–908.

crack growth wherein adsorption of species from the environment, including hydrogen, facilitates dislocation emission from the crack tip, leading to a highly localized plastic fracture.<sup>152</sup> As he points out, both mechanisms involve the weakening of bonds between metal atoms, and some proportionality between the resulting crack growth rates might be expected. A strength of Lynch's proposal is that it easily encompasses liquid metal and hydrogen embrittlement,

whereas these are treated a little vaguely in the SMM. Like Galvele, Lynch cites particular experiments showing very high crack velocities, to argue against dissolution or other bulk effects, but with more justification, in that the cracking of nickel monocrystals in mercury or hydrogen does seem to be a continuous process without crack jumps, whereas Galvele's studies of SCC in noble-metal alloys<sup>182</sup> claim continuous crack velocities of up to  $20 \text{ mm s}^{-1}$ , but are

**Figure 42** The AIDE mechanism. Reproduced from Lynch, S. P. In *Corrosion/2007*; NACE: Houston, TX, 2007; Paper No 489.

contradicted by the experimental evidence for large brittle crack jumps in such systems.<sup>166</sup>

From an energetic point of view, the Lynch mechanism, or adsorption induced dislocation emission (AIDE) relies on the occurrence of intense plasticity within a very small volume at the crack tip. This can lower the total energy of fracture, which is integrated over the whole deformed volume around the crack. The proposed micromechanism is shown in Figure 42.

A possible weakness of the AIDE mechanism used to be the insistence on a truly 2D interaction rather than any 3D reaction mechanism. Nowadays, Lynch tends to accommodate a near-surface process zone, although in the case of LME in immiscible systems, this must be very shallow. An intriguing suggestion, based on first-principles calculations for Ga on Al, is that LME systems, bulk-miscible or not, are those in which there is facile alloying of the liquid metal into the first one or two atomic layers of the substrate.<sup>183</sup> Since surface alloying is also known in vacuum deposition and in underpotential deposition of metals on copper and other substrates,<sup>184,185</sup> this raises the interesting possibility that – for example – Pb ions could cause cracking of copper or other metals by an underpotential displacement reaction followed by a LME-type cracking.

Other local softening models exist, such as that of T. Magnin, which although mainly developed for hydrogen effects<sup>153</sup> has also been applied to ‘anodic’ SCC.<sup>186</sup> Such softening may very well occur – the question is whether, in a given instance, it is essential for cracking. In corrosion fatigue, it is well-established that ordinary active dissolution in noble metals like copper can promote cracking,<sup>187</sup> and so the dissolution must be enhancing plasticity, since

fatigue is essentially a plastic fracture (no evidence of brittleness is seen on such fractures). So it is not at all unreasonable to propose a similar effect in SCC, at least where dynamic straining is applied externally, as in a SSRT.

\*It is the intention in this chapter to discuss some of the more recent developments in the field of corrosion fatigue. Given the previous edition's emphasis on long crack growth, much of this chapter is devoted to an understanding of the early stages of corrosion fatigue, often termed the 'initiation' stage.

$K_{\min}$	Minimum stress intensity
$K_t$	Stress concentration factor
$m$	Constant
$m1, m2, A, \text{ and } x$	Experimentally determined constants
$N$	Number of cycles
$N_f$	Number of cycles to failure
$Q$	Function based on crack shape
$R$	Stress ratio
$r_p$	Size of the plastic zone
$t$	Time
$t_{p/c}$	Time to pit/crack transition
$\gamma$	Shear strain
$\gamma_{eq}$	Equivalent strain
$\Delta K$	Crack tip stress intensity factor range
$\Delta K_{th}$	Threshold stress intensity factor
$\sigma$	Stress
$\sigma_a$	Stress amplitude
$\sigma_y$	Yield strength

### 2.12.1 Introduction and Historical Perspective

The term *fatigue* was coined in the latter half of the nineteenth century, although this type of failure had previously been recognized in the early 1800s as a different type of fracture occurring in the axles of the railway locomotives and carriages. In 1843, Rankine<sup>1</sup> attributed this behavior to a gradual deterioration of the material during its service life. Other views held at the time were that the metal had become tired, lost its nature, or crystallized.

Fatigue cracking<sup>2</sup> is a consequence of highly localized plastic deformation, where the vast majority of cracks start at a free surface. However, it is not necessary for the bulk of the grains in a piece of metal to deform plastically for it to fail by fatigue, and continued cyclic plastic deformation in one localized surface region is sufficient for fatigue failure to occur. This aspect distinguishes the problem from any other form of mechanical failure, the basic features of fatigue failure being the ‘initiation’ of surface microcracks and their subsequent propagation through the bulk of the material.

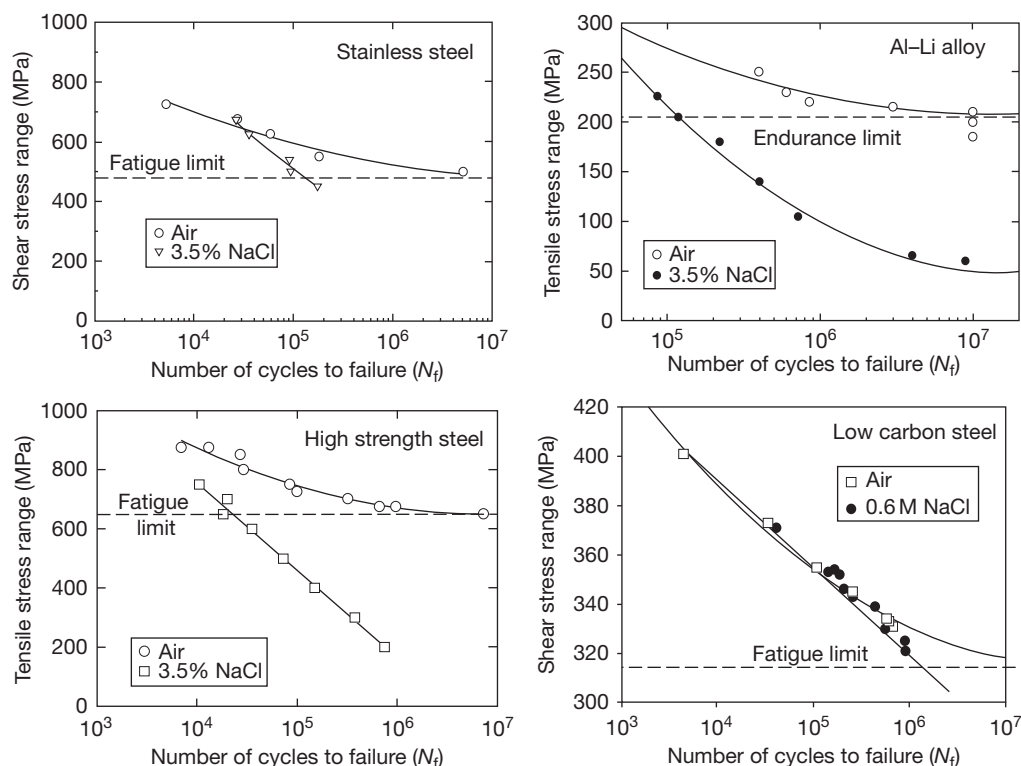

*Corrosion fatigue* is a term used to describe cracking (including both initiation and growth) in materials subject to the combined actions of a fluctuating (cyclic) stress and corrosion. Electrochemical reactions taking place at the metal–environment interface govern whether the mechanism of failure is controlled

by anodic dissolution or hydrogen embrittlement. Unlike the phenomenon ‘*stress corrosion cracking*’ where cracking is often controlled by specific combinations of material–environment, for example, brass in ammonia-containing environments, this specificity rarely applies in this type of cracking process. In fact, environments as innocuous as moist air can lead to severe reductions in the fatigue resistance of high-strength engineering alloys.<sup>3</sup>

Haigh<sup>4</sup> published possibly the earliest recorded paper on corrosion fatigue while seeking to explain the failure of towing ropes that were kept in a state of frequent vibration when exposed to sea water. Later work by McAdam<sup>5</sup> and Gough<sup>6</sup> laid the foundations for work on the subject of corrosion fatigue. McAdam’s work showed the danger of adopting higher-strength alloy steels in preference to ordinary steels. It is now established that an increase in tensile strength of low corrosion-resistance alloys is associated with a decreased resistance to corrosion fatigue. McAdam’s work also included the connection between pitting and cracking and showed the time-dependency effects due to corrosion by studying the effects of frequency of loading on fatigue lifetime. The influence of the environment on fatigue is assessed by plotting the relationship of stress to number of cycles to failure, the so-called ( $S$ – $N$ ) curve. Figure 1 shows the results of  $S$ – $N$  tests on different substrates in a 3.5% NaCl solution at open-circuit potential and open to the atmosphere. Here, it can be seen that the most significant impact of the environment is seen at stress levels close and below the in-air fatigue limit, a region that might historically have been deemed the ‘crack initiation’ region. As will be discussed later, it is now known that the environment has a major effect on the early stages of crack growth in the microstructural fracture mechanics regime.<sup>7</sup>

The electrochemical aspects of corrosion fatigue were clearly demonstrated in the studies of Evans and Simnad.<sup>8,9</sup> An important aspect of this work included observations showing an increase in corrosion rate with increase in applied stress (see Section 2.12.3). These results highlighted an increase in metal dissolution when the degree of plasticity increased. Furthermore, it was noted that when the material was subject to stresses within the elastic range, the rate of corrosion hardly differed from when the material was unstressed.

Another feature of this work included the effects of an applied cathodic current. In this case, it was found that fatigue lives were enhanced in neutral salt solutions, in which the rate of metal dissolution at potentials below the open-circuit potential was

**Figure 1** S-N curves for various alloys in 3.5% (0.6M) NaCl. Reproduced from Miller, K. J.; Akid, R. *Proc. R. Soc. Lond. A* **1996**, 452, 1411–1432.

negligible. For acidic solutions, a greater applied cathodic current was required for protection before an equivalent improvement in fatigue life was observed. The conclusion given was that ‘while elastic deformation does not affect the chemical or electrochemical properties of the iron, deformation beyond the elastic limit (which may occur if pits produce stress intensification) alters these properties, making the iron behave like a more reactive metal. This behavior was later confirmed by measuring the growth rates of pits under different values of stress (see [Section 2.12.3.1.2](#)).

The following sections of this chapter will address the mechanisms and factors affecting the fatigue life of various engineering alloys operating within corrosive environments.

## 2.12.2 Fundamentals of Fatigue Failure

Before going on to discuss corrosion fatigue in detail, it is worthwhile briefly outlining the basic fundamentals of fatigue in the absence of an environment. Given this

understanding, it is considered that the reader will better appreciate the role of the environment in the corrosion fatigue process.

Fatigue damage is responsible for around 70–80% of the rupture cases of mechanical engineering components and structures in the world; therefore, an understanding of how cracks initiate and propagate would be useful when designing these structures.

It is generally accepted that purely elastic deformations are totally reversible and do not induce damage. Furthermore, it is accepted that fatigue rupture is related to the localization of plastic deformation,<sup>10</sup> and during cyclic loading, the following occurs<sup>11</sup>:

- cyclic softening or hardening: at constant strain amplitude, the stress amplitude decreases or increases respectively,
- crack development via surface intrusion and extrusions,
- crack propagation.

The main site for crack initiation is generally the material surface, as the surface grains may deform plastically and crack more easily than other grains,

because not only are they in contact with the environment, which has a great role in fatigue damage, but they are also the only ones not totally surrounded by other grains, that is, unconstrained.

Initiation sites most frequently encountered include the material surface defects – stress concentrations near notches, corners, holes, etc. In the case of smooth specimens, without any macroscopic defects, slip bands form at the surface on activated slip systems in grains favorably oriented. These slip bands are associated with intrusions/extrusions, see **Figure 2**, which may act as crack initiation sites.

For some materials, such as body-centered cubic (bcc) alloys, initiation may be intergranular owing to shape changes of the near surface; this leads to deformation incompatibility which in turn contributes to localized deformation irreversibility at the grain boundaries. This effect has been attributed to the, thermally activated, so-called asymmetric glide of the screw dislocations in tension and compression.<sup>10,13</sup> Also, crack initiation very often takes place at interfaces such as inclusion/matrix or second phase/matrix.

There appears to be no real distinction between crack initiation and crack propagation, just as it is difficult to know when a slip band becomes a crack. **Figure 3** presents a schematic of the development of a crack from a free surface, while **Figure 4** relates the crack growth rate with the crack size and the relevant crack growth regime.

**Figure 3** shows that a crack initiates from the free surface, usually in the largest grain along a shear slip plane at  $45^\circ$  to the loading axis. Plasticity induced in the grain drives the crack until a dislocation build-up occurs as the crack tip approaches the grain boundary between grains 1 and 2. As the crack tip approaches the first grain boundary ( $d_1$ ), in **Figure 4**, the growth rate of the crack decreases. There are now two possible outcomes depending upon the level of the applied stress; if the stress is below the fatigue limit, the crack decelerates and may arrest, and if the stress level is above the fatigue limit, the crack grows into the next grain and can continue to propagate throughout the structure. A revised definition of the fatigue limit might be ‘the stress level where a crack does not propagate beyond a defining microstructural dimension.’ This dimension being one or several grains or a value related to the microstructure, for example, martensite lath size or prior austenite grain boundary size. At and around the fatigue limit, the ‘short’ crack growth behavior is very nonlinear. This nonlinear

**Figure 2** Formation of intrusions and extrusions at persistent slip bands (PSBs) during fatigue loading. Reproduced from Forsyth, P. J. E. *J. Inst. Metals* **1951/2**, 80, 181.

**Figure 3** Schematic illustrating different fatigue crack growth stages.

**Figure 4** Fatigue crack growth rate as a function of crack size.

'short crack' growth behavior continues as the crack propagates through the microstructure. However, as the crack tip stress intensity increases with crack length, the effective barrier resistance of the grain structure diminishes until the crack growth is unaffected by the microstructure. At this point, the ratio of the crack tip plastic zone size to crack length is around 0.02, and the crack may be considered to fall within the linear elastic fracture mechanics (LEFM) regime and is described as a 'long crack' (see Section 2.12.4.2).

The first two crack growth stages (A and B) shown in Figure 4 have 'historically' been considered as the *initiation* stage, while the third regime (C) is the representative of the *propagation* stage. The variables affecting each of these stages are further discussed in Section 2.12.4.

### 2.12.3 Corrosion Fatigue Regimes, Mechanisms, and Modeling

The following section is aimed at addressing the different regimes that contribute to the damage processes of pit and crack development and subsequent growth of corrosion fatigue cracks. The section is divided into the growth of defects (pits and cracks) from smooth surfaces and the growth of preexisting long cracks. The examples given in this section relate predominantly to steels actively corroding within chloride environments; however, where appropriate, work illustrating other metal/environment systems is also discussed.

#### 2.12.3.1 Initiation and Short Crack Growth

It has recently been recognized that cracks develop very early in the lifetime of a component and that the fatigue crack initiation period is considered to be a negligible phase in the fatigue failure process.<sup>14,15</sup> The premise is that fatigue cracks initiate below the fatigue limit but the rate of propagation is controlled by numerous factors and under some cases this rate is sufficiently small to be considered negligible, leading to infinite fatigue life. An important point here is that if the conditions change, for example, a fatigue load excursion above the fatigue limit stress, the propagation rate may change causing the crack to grow beyond a critical threshold size.

The corrosion fatigue process may be considered analogous to that of air fatigue, notably because damage occurs very early in life and the defect, pit or

crack propagates at a rate governed by the loading/environmental conditions. As will be discussed later, processes such as passive film breakdown and pitting play an important role in contributing to the early stages of damage, Figure 5.

Figure 5 shows the typical development stages for air and corrosion fatigue cracking. In air, a crack develops on the surface at some defined size,  $a_0$ , often related to the surface roughness or a metallurgical feature such as an inclusion, and then grows up to the major microstructural barrier. If the stress level is not above the fatigue limit, crack arrest occurs and a nonfailure condition exists. If the stress level is just above the fatigue limit, the crack can grow beyond the major microstructural barrier and a failure condition exists. Under corrosion fatigue conditions, surface film breakdown or local microgalvanic activity occurs leading to localization of corrosion (pitting). Subject to the nature of the environment, pit growth continues until a transition to cracking occurs. Environment-assisted crack growth then ensues until failure occurs.

In terms of fatigue life, the most important regimes are (a) in air, the stage I (shear) to stage II (tensile) crack transition; Figure 3 and (b) in corrosion fatigue, the pit-crack transition. These regions are highlighted in Figure 5. At this point, the crack is propagating at its lowest rate. A similar feature is observed for corrosion fatigue loading.<sup>7</sup> In the case of air fatigue, the microstructural barriers impede crack growth; in corrosion fatigue, pit growth rate

**Figure 5** Schematic showing the behavior of fatigue cracks under air and corrosion fatigue conditions. Note that the stress level for the corrosion fatigue curve is less than the in-air fatigue limit of the material. Individual annotated regimes are for corrosion fatigue only. Reproduced from Akid, R. In *Effects of Environment on the Initiation of Crack Growth*; Van der Sluys, W. A., Piascik, R. S., Zawiercha, R., Eds.; ASTM STP 1298, 1997, pp 1–17.

decreases (see Figure 8) as it is governed largely by solution chemistry and electrochemistry, which change as the pit size increases. Akid<sup>16</sup> undertook a comparison of these transition regimes in a high-strength steel for fatigue in air and in 0.6 M NaCl (see Figure 6). The following main conclusion can be drawn: the stage I to stage II transition in air takes place at a greater fraction of lifetime and at defect sizes larger than that of the pit/stage II transition (see shaded regions). The implication of this result is that stage II tensile cracking can be promoted by the presence of a pit and occurs earlier in the lifetime of a component subject to corrosion fatigue when compared to identical loading conditions in the absence of the environment, that is, air fatigue loading.

The term ‘crack initiation’ has generally been considered as that period prior to the observation of a crack. This leads to a problem, notably, ‘when is a crack observable?’; hence quantification of the period of initiation becomes subjective and dependent upon the equipment being used to monitor the surface. This problem was recognized by Ford<sup>17</sup> who proposed that initiation, under environment-assisted cracking conditions, comprises only the time required to form a localized environment and as all surfaces contain geometrical discontinuities, this period, relative to the total lifetime, will comprise only a few percent. This is in keeping with the premise that propagation dominates the damage process.

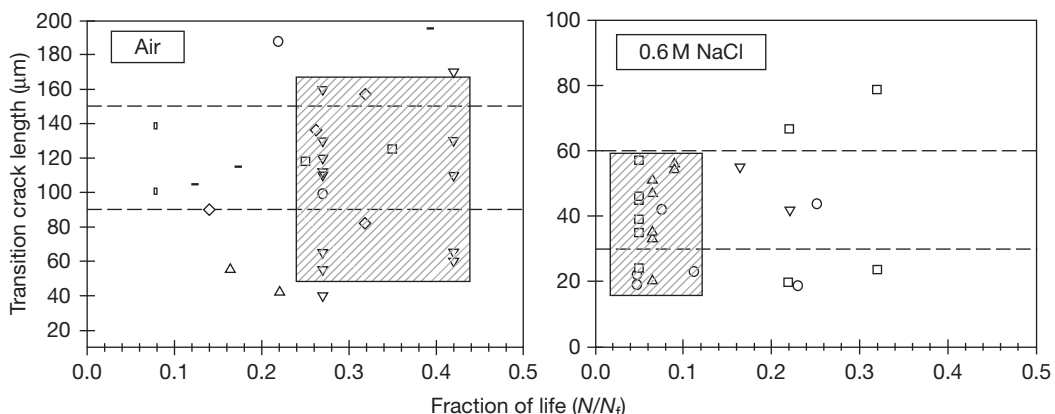

### 2.12.3.1.1 Passive film breakdown and pitting

Many commercial alloys contain inclusions, and these can provide the sites for crack initiation in both air and corrosion fatigue. Inclusions are chemically

different to the matrix in which they are contained and therefore will have a different electrochemical behavior to that of the matrix. Furthermore, the passive film developed over the site of an inclusion will differ primarily in its chemistry and thickness from the passive film formed on the matrix. The consequence of this is that these sites are preferentially attacked in the presence of depassivating agents such as chloride ions; for example, AlCu-type inclusions in AA2024 alloys suffer preferential chemical attack and can promote pitting.<sup>18</sup>

The effect of pitting on a component's fatigue life was demonstrated in the early work of McAdam,<sup>5</sup> and Evans and Simnad<sup>8,9</sup> in which it was shown that pre-pitting a specimen prior to air fatigue testing results in pits acting like notches, thereby lowering the fatigue limit. However, pre-pitting tests differ significantly from full immersion or cyclic immersion corrosion fatigue tests, which will be discussed later. Jack and Paterson<sup>19</sup> concluded, in their work on three turbine rotor shafts (2% Cr/Ni/Mo/V steel), that cracks initiated at corrosion pits and grew by high cycle fatigue. Metallographic examination of the rotor shafts showed that pits were widely distributed and some pits were present without cracks while all the cracks had initiated at pits. This would seem to imply that in these materials, cracking occurs after the onset of pitting and not the reverse.

Conversely, Duquette and Uhlig<sup>20</sup> argued that initial pit formation is not a requirement for corrosion fatigue. Evidence from their research suggested that the applied stress level determines whether cracks develop from pits or from slip bands. At high-stress levels, slip bands form quickly with insufficient time for pit formation to take place; hence slip-band

**Figure 6** Comparison of stage I crack/stage II crack and pit/stage II crack transition for a high-strength carbon steel ( $\sigma_y$ : 1440 MPa) in air and 0.6 M NaCl. Fully reversed torsion. Reproduced from Akid, R. In *Effects of Environment on the Initiation of Crack Growth*; Van der Sluys, W. A., Piascik, R. S., Zawiercha, R., Eds.; ASTM STP 1298, 1997, pp 1–17.

cracking dominates. It should be clarified that the above study relates to the work carried out on 0.18% C steel at pH values of 2–4. However, the development of pits or slip-band dissolution was observed to be dependent upon solution conditions as shown by Akid<sup>21</sup> who, using a similar steel, showed that pitting was the preferred corrosion mechanism at near-neutral pH values, while at pH 2, slip-band dissolution was the dominant process.

Magnin<sup>22</sup> described the effects of the stress–environment interaction on dislocations, illustrating that such interactions increase the dislocation density at the crack tip causing a more localized form of damage than would occur in the absence of the environment.

From the above discussion, it is therefore clear that substantial evidence exists for pitting to be one of the principal mechanisms for the initiation of corrosion fatigue cracks. Leis *et al.*<sup>23</sup> summarized some of the effects that are attributable to pitting, suggesting that pitting may accelerate the initiation process through a mechanical notch effect; pits may concentrate aggressive chemical species in the environment and that pits may serve to raise locally the stress above yield in a nominally elastically loaded material. The following section provides a summary of the influence of different variables on the development and growth of short cracks. From the results of numerous tests conducted under a wide range of conditions, a model is proposed for predicting corrosion fatigue lifetime.

### **Surface films and film breakdown**

With the exception of some of the noble metals, the majority of engineering metals and alloys exist with a surface film that offers corrosion protection to a greater or lesser degree. Classically, this is seen in the range of alloys known as the *stainless steels*. Stainless steels contain greater than 12% Cr which, along with other alloying elements, gives rise to a mixed oxide surface film having a thickness of the order of tens of nanometers. Similarly, the corrosion resistance of Al and Al alloys is attributed to the presence of a thin aluminum oxide film.

As previously discussed, fatigue and corrosion are both highly localized surface phenomena. The nature of the metal surface, in conjunction with the chemistry of the electrolyte, therefore plays a significant role in establishing the type and degree of damage arising during corrosion fatigue. As discussed above, the inherent resistance of a material to corrosion is

based upon the properties of the surface film. Breakdown of this film leads to the separation of anode and cathode sites and to the development of localized corrosion, for example, pitting. The ability to overcome this resistance to surface damage might therefore be seen as a ‘primary threshold’ with pit growth occurring above this threshold. A value for this threshold would be dependent upon the nature of the oxide film, notably its mechanical and chemical properties and thickness,<sup>24</sup> the nature of the electrolyte,<sup>25,26</sup> and the magnitude of applied stress to which the film is subjected.<sup>26</sup>

### **Pitting**

The association of pits as precursors to crack initiation was demonstrated over 70 years ago by McAdam.<sup>5</sup> Recent corrosion fatigue studies<sup>27–29</sup> have shown that pitting is often associated with inclusions or constituent particles lying within the matrix of the alloy, for example, manganese sulfide in steel. The chemical nature, size, and distribution of such particles play an important role in the early stages of corrosion fatigue damage.

Muller<sup>30</sup> considered the influence of early fatigue crack growth based on crack initiation as the failure criteria. A model was proposed based on corrosion kinetics and fracture mechanics featuring three different corrosion conditions: general, pitting, and passive corrosion. In the case of pitting corrosion, the lifetime is determined by a critical pit depth from which a fatigue crack can develop. In passive corrosion conditions, the lifetime is determined by slip characteristics and repassivation kinetics leading to a critical corrosion current below which no corrosion fatigue cracks can initiate. Experimental results from crack initiation tests on chromium–nickel steels showed good correlation with the theoretical models. The model further proposed that all the three modes of corrosion are dependent upon the applied stress.

An extended discussion of the influence of stress on pitting and pit growth rates can be found from Akid.<sup>16</sup> In summary, it is suggested that pit growth rate is influenced by the degree of plasticity within the grains surrounding the pit and that boundary conditions exist for the effects of stress on pit growth rate, these being the onset and saturation of plastic deformation (see **Figure 7**). The pit growth rate coefficient is based upon measurements of pit size prior to the pit–crack transition. This influence of stress on pit development/growth is supported by

**Figure 7** Influence of stress on pit growth rate coefficient. Q2N steel (0.12%C),  $\sigma_y = 790$  MPa; 3 pt bend testing,  $R = 0.01$ ; in artificial seawater. Derived from experimental data from reference. Reproduced from Wu, X. J. Ph.D. Thesis, University of Sheffield, 1995.

work recently conducted concerning the electrochemistry of deformed smooth surfaces.<sup>32</sup>

#### Pit/crack transition

It has been demonstrated above that pits act as sites for crack initiation and that pit growth rate is a function of material, environment, and loading conditions. The transitional stage from a pitting (time-dependent) dominated regime to that of a mechanical (cycles-dependent) regime is a critical stage in the corrosion fatigue process. Recent results<sup>33</sup> have shown that, not surprisingly, this transition stage is dependent upon local solution chemistry, stress, and time. Interestingly, during this study, which concerned the corrosion fatigue of two thermo mechanically processed steels, one containing Mo/V additions and one without, the transition times and dependencies on stress were different; however, the lifetimes were similar. This arose because the pit size at which the transition occurred differed between the two steels. Unfortunately this makes modeling of corrosion fatigue slightly more complex than would ideally be desired. However, given sufficient statistical confidence, it would be possible to develop a model based upon a 'process-competition' approach in which stages were assigned depending upon the dominant process, that is, stress-assisted pitting and dissolution-assisted cracking. Such an approach is described in Akid.<sup>16</sup>

An example of the pit-to-crack transition from the study by Ebera<sup>34</sup> is given in **Figure 8**. Here, it can be seen that a significant number of cycles elapses before a crack initiates from the pit. Ebera found that the

maximum depth of the corrosion pit at the crack initiation stage is  $23.5 \mu\text{m}$  in plane bending at a stress of 228 MPa ( $N/N_f = 0.968$ ) and  $17.8 \mu\text{m}$  in plane bending at a stress of 280 MPa ( $N/N_f = 0.645$ ). However, it should be noted that the test frequency used in this study was 60 Hz which gives times for the pit-to-crack transition of 23 and 9 h, respectively for stress levels of 228 and 280 MPa.

The relationship between stress and time to the pit-crack transition for Ebera follows the trend observed by Akid<sup>31</sup> who correlated data for a range of steels tested in chloride environments under different loading conditions (see below) and found the following trend:

$$t_{p/c} = (A/\sigma)^C$$

where  $t_{p/c}$  is the time to pit-crack transition in seconds,  $\sigma$  is the applied stress in MPa, and  $A$  and  $C$  are constants dependent upon material, environment, loading mode, and test frequency.

**Figure 9** presents the analysis of nine different studies where the corrosion fatigue mechanism involved a pit-crack transition. The numbers in square brackets given in the figure refer to references cited in Akid.<sup>16</sup> These data represent steels tested under torsion, uniaxial, rotating bending and 3 pt bend loading at different frequencies within chloride environments.

#### Physically short crack/long crack interface

It is well established for both air and CF cracking that short cracks grow at rates many times that of 'ΔK equivalent' long cracks.<sup>35</sup> Subject to the limitations of calculating ΔK values for small defect sizes, **Figure 10** shows that conventional LEFM analyses are not appropriate for predicting the transition from pitting to cracking. At longer crack lengths, there is a good correlation between smooth specimen tests and LEFM test data. The data in **Figure 10** suggest that there is a greater correlation between physically short cracks and long cracks close to  $\Delta K_{th}$  and that the pit-to-crack transition may be independent of the stress intensity factor. This degree of correlation between short and long crack growth rates shows the value of conducting short crack corrosion fatigue tests, notably that information on both microstructural short crack behavior and 'long crack' thresholds can be obtained using short crack test methods.

As discussed previously, in particular for passive metals/alloys, the early stages of corrosion fatigue often involve local breakdown of the passive film

**Figure 8** CF crack development of a pit: 12% Cr stainless steel; 3.5% NaCl; stress level 228 MPa (after 34); cycles elapsed, (a)  $4.950 \times 10^6$  (b)  $5.450 \times 10^6$  (c)  $5.480 \times 10^6$  (d)  $5.485 \times 10^6$  (e)  $5.495 \times 10^6$  (f)  $5.515 \times 10^6$  (g)  $5.500 \times 10^6$ .

followed by active corrosion, that is, pitting. This time dependent corrosion phase eventually gives way to crack formation and a transfer into a 'predominantly' mechanical, fatigue-cycles dominated regime. The characterization of these features, summarized in **Table 1**, is based upon numerous studies during which damage is monitored via a plastic replication technique.<sup>28,33,36–40</sup>

An alternative model, appropriate for slip-band cracking is given in **eqn [3]**.

On the basis of these studies and equivalent tests conducted in an air environment, the following simple models have been proposed<sup>37,42</sup> which account for the individual stages identified in **Table 1**. These models are either based upon a modified in-air short crack growth model<sup>37</sup> or on the degree of plasticity at the

crack tip,<sup>42</sup> see **eqns [1], [2], and [3]**, respectively.

$$\frac{da}{dN} = A\gamma^\alpha (d - a) \text{ MSC} \quad [1]$$

$$\frac{da}{dN} = B\gamma^\beta a - D \text{ PSC} \quad [2]$$

where MSC and PSC represent the microstructural short crack and physical short crack regimes, respectively.  $A$ ,  $B$ ,  $\alpha$ , and  $\beta$  are constants depending upon material and environment;  $\gamma$  is the shear strain, and  $d$  is a microstructural dimension, for example, grain size,  $a$  is the defect size, that is, pit size or crack length, and  $D$  is the LEFM threshold crack growth rate.

**Figure 9** Relationship between time to pit-crack transition and applied stress for various steels. Reproduced from Akid, R. In *Effects of Environment on the initiation of Crack Growth*; Van der Sluys, W. A. Piascik, R. S., Zawiercha, R., Eds.; ASTM STP 1298, 1997, pp 1–17.

**Figure 10** Comparison of short and long corrosion fatigue crack growth rates for a C-steel ( $\sigma_y = 500$  MPa). Conditions: artificial seawater at OCP and uniaxial loading at a stress ratio,  $R = 0.1$ . Note open symbols represent data from smooth specimen short crack tests and solid symbols represent data from pre-cracked specimens.  $\Delta K$  values for short cracks are based upon an average crack shape aspect ratio and geometry factor of 0.65–0.7 depending upon crack size. Reproduced from Akid, R. In *Effects of Environment on the initiation of Crack Growth*; Van der Sluys, W. A. Piascik, R. S., Zawiercha, R., Eds.; ASTM STP 1298, 1997, pp 1–17.

**Table 1** Designated damage regimes relating to the early stages of corrosion fatigue

Damage regime	Process	Influential factors
1	Pitting	Solution composition, pH, applied stress
2	Pit/crack transition	Pit shape/local pit environment, applied stress state
3	Environment-assisted short fatigue crack growth	Local crack tip chemistry, applied stress state
4	Physically short crack growth	Applied stress state ( $\Delta K$ )

$$\frac{da}{dN} = C(r_p)^m \quad [3]$$

Here,  $C$  and  $m$  are constants depending upon material and environment, and  $r_p$  is the size of the plastic zone.<sup>31</sup>

Where the applied stress state differs from a uniaxial loading condition, for example, fully reversed torsion or tension, a modification is made to eqns [1], [2], and [3] in which  $\gamma$  is replaced by  $\gamma_{eq}$ , an equivalent strain based upon the multiaxial loading condition in which both the principal strain and the strain normal to the shear plane are taken into account.<sup>43,44</sup>

While this approach offers a number of advantages in terms of the application of LEFM analyses, it does not recognize that pit growth is influenced by the microstructural state and that the transition from a pit to a crack is influenced by plasticity. This latter effect has significant implications for the application of LEFM to such small defects. This can be seen in **Figure 10** which shows pit–crack transitions occurring well below the LEFM threshold.

Modeling corrosion fatigue behavior, like modeling air fatigue, has fallen into two main categories based upon the existence or otherwise on a defect. Typically, the models address either the development and growth of defects (initiation) or the propagation of defects which fall under the boundary conditions of LEFM.

### 2.12.3.1.2 Pitting corrosion fatigue models

As discussed in the previous section, initiation is commonly referred to as the ‘nucleation stage,’ that is, the beginning of defect development. Unfortunately, this can cause uncertainty with the accuracy in prediction of lifetime, as nucleation is somewhat dependent upon the first observation of a defect (crack or pit). Initiation might also be defined as ‘life to a certain detectable defect size.’ This subtle distinction requires that designers carefully consider the ‘inspectability’ or ‘detectability’ of a component or structure. A number of researchers have also suggested that stress intensity factor can be used to define specific stages of the CF process.<sup>45, 46</sup> Given that pitting corrosion is often a precursor to fatigue crack development, this section will provide details on pitting corrosion fatigue models developed to predict CF lifetime. These models are based upon the damage mechanism that consists of the formation of a pit and eventual

development of a crack from the pit site. A more detailed review of this subject is given by Hagn.<sup>47</sup>

The models of Hoepfner,<sup>45</sup> Lindley,<sup>48</sup> Kawai,<sup>49</sup> Kondo,<sup>50</sup> and Chen<sup>51</sup> rely on a transition from pitting to cracking defined by a stress intensity threshold value ( $\Delta K_{th}$ ) or that the stress intensity associated with a pit can be defined based upon its geometry, often assuming the pit is hemispherical. **Table 2** summarizes the approaches adopted by these authors.

One major problem that has not been addressed when applying a fracture mechanics approach to corrosion fatigue lifetime prediction of nondefective surfaces is the important point that LEFM analyses tend to assume that cracks do not propagate below the  $\Delta K_{th}$  value. Yet it is known that cracks do initiate at pit sites below the threshold value (calculated using the dimensions of the pit), as illustrated in **Figure 10** above. In considering the results shown in **Figure 10**, the role of crack closure should be considered. Corrosion may affect crack closure in two ways, notably: corrosion can lead to oxide film formation on the crack walls, leading to an increase in closure, or corrosion can remove material by dissolution, leading to a reduction in crack closure. Crack closure is associated more with long cracks than with short cracks because of the limited crack opening displacement of small defects.

### 2.12.3.2 Long Crack Growth

Differentiation of ‘short’ and ‘long’ crack growth is normally made based upon the degree of yielding or plasticity occurring at the crack tip. Knott<sup>52</sup> has shown that LEFM analysis is applicable when the plastic zone size ( $r_p$ ) is less than one-fiftieth (1/50) of the crack length.

**Table 2** Summary of pitting corrosion fatigue models

Author	Model	Comments
Hoepfner <sup>45</sup>	$K = 1.1\sigma\sqrt{\pi\frac{a}{Q}}$ and $t = \left(\frac{d}{c}\right)^3$	$\sigma$ = applied stress, $a$ is pit length, $Q$ is a function based on crack shape, $t$ is time to attain pit depth for corresponding threshold value, $d$ is pit depth, and $c$ is a constant dependent upon material and environment
Lindley <sup>48</sup>	$K_{th} = \frac{\Delta\sigma\sqrt{(\pi a)[1.13 - 0.07(a/c)^{0.5}]}}{[1 + 1.47(a/c)^{1.64}]^{0.5}}$	Pits considered as semielliptical cracks. $a$ is a minor and $c$ is a major axis of semielliptical crack
Kawai <sup>49</sup>	$\Delta\sigma = \frac{\Delta K_{all}}{F\sqrt{\pi h_{max}}}$	$\Delta K_{all}$ determined from $da/dN$ vs. $\Delta K$ plot. $F$ is a geometry factor and $h$ is maximum pit depth
Kondo <sup>50</sup>	$\Delta K_p = 2.24\sigma_a\sqrt{\pi c\alpha/Q}$ and $c = C_p(N/f)^{1/3}$	Assumes pit as a crack, $\sigma_a$ is stress amplitude, $a$ is aspect ratio (assumed constant) and $Q$ is a shape factor. $C$ is pit radius, $N$ , number of fatigue cycles, and $f$ is cyclic frequency
Chen <sup>51</sup>	$\Delta K_{tr} = (1.12K_t\Delta\sigma\sqrt{\pi c_{tr}})/\Phi = \Delta K_{th}$	$K_t$ is a stress concentration factor, $c$ is half-pit diameter and $\Phi$ is a shape factor determined by the pit diameter and depth

For uniaxial loading, the size of the plastic zone is given by eqn [4].

$$r_p = \frac{1}{2\pi} \left[ \frac{\Delta K_I}{2\sigma_y} \right] \quad [4]$$

where  $K_I$  is the stress intensity factor ( $\text{MPa} \sqrt{\text{m}}$ ) and  $\sigma_y$  is the yield strength (MPa).

A bounding condition for LEFM applicability is therefore the relationship between  $r_p$  and the crack length, as previously described.

Unlike the  $S$ - $N$  tests, which use smooth ‘defect-free’ specimens, LEFM test methods use a precracked specimen, which is subject to fatigue cycling within the desired environment. Measurements of crack length are taken at selected intervals at a specified stress ratio (minimum/maximum load). The results of this type of test are presented in a fatigue crack growth rate curve as shown in Figure 11. Here, LEFM long crack growth is associated with the stage II regime of the crack growth rate diagram and is often called the ‘Paris’ region.<sup>53</sup> This region is defined by the empirical relationship given in eqn [5];

$$\frac{da}{dN} = C(\Delta K)^m \quad [5]$$

where  $\Delta K = K_{\max} - K_{\min}$ , and  $A$  and  $m$  are material-, temperature-, microstructure- and stress-ratio-dependent constants. Values of  $m$  that have been reported in the literature lie typically in the ranges of values  $2 \leq m \leq 5$ . This equation is widely used in its integrated form to evaluate the lifetime of cracked structures knowing the stress field, the threshold and critical values of  $K$  and the constants  $A$  and  $m$ .

This empirical relation given in eqn [5] contains the self-similarity of the fatigue crack growth process. However, it is only valid within a so-called intermediate, medium-amplitude part of the fatigue kinetic diagram (stage II), as shown in Figure 11.

A threshold effect is observed,  $\Delta K_0$  (or  $\Delta K_{th}$ ), which occurs when the crack growth rate equals a value of approximately the order of one atomic spacing per cycle. Hence the plot is generally divided into three regions. When the maximum stress intensity factor becomes higher, the crack growth curve deviates from linearity (the ‘Paris’ region), and crack instability and rapid acceleration can occur terminating in failure (stage III).

In stage I, the crack growth rate is very low, and experimental data have shown that the crack growth in this region is greatly affected by microstructure, environment, and stress ratio.<sup>54–57</sup>

The self-similitude concept postulates that cracks of different lengths will have the same stress and strain fields, and hence the same crack growth rate if they are subject to the same applied  $\Delta K$ . This means that cracks in specimens and structures can be directly compared. However, small-scale yielding (SYY) conditions are assumed to prevail, where SYY is dependent upon crack opening displacement and a nonhardening material. This leads to the condition that the limiting stress amplitude is less than one-third of the yield stress. More generally, for this concept to hold, low applied stress levels are required.

Substantial work on the relationship between  $\Delta K$  and the crack growth rate followed on from the work of Paris and Erdogan, although it was not until the

**Figure 11** LEFM fatigue crack growth curves showing behaviour for air, corrosion fatigue and corrosion fatigue plus stress–corrosion interactions.

early 1970s that an international conference was held<sup>58</sup> to review the subject of corrosion fatigue.

As can be seen from the schematic in Figure 11, the environment generally causes an increase in the crack propagation rate for a given  $\Delta K$  value. Furthermore, crack growth rate can be further augmented if the material is also susceptible to stress corrosion cracking within the test environment.

### 2.12.3.2.1 LEFM-based corrosion fatigue models

There are numerous models cited in the literature that attempt to quantify the contribution from both electrochemistry and the mechanical loading condition. These models may be characterized under the following categories: process superposition, process competition, and process interaction.

Wei and Landes<sup>59</sup> first proposed a *process superposition model*, which summed the stress corrosion component of crack growth with that of air fatigue crack growth. The model can be expressed as eqn [6].

$$(da/dN)_{cf} = (da/dN)_r + \int da/dt K(t) dt \quad [6]$$

where  $(da/dN)_{cf}$  is the rate of fatigue crack growth in an aggressive environment,  $(da/dN)_r$  is the rate of fatigue crack growth in an inert environment, and the integral term is the environmental contribution obtained from sustained load crack growth in the same environment. This model takes no account of any synergistic interactions between corrosion and fatigue. Later refinements of this approach were predicated on the recognition that environmentally assisted crack growth is the result of sequential processes and is controlled by the slowest process in the sequence.<sup>60</sup>

Austen and Walker<sup>61</sup> proposed the *process competition model* on the basis that stress corrosion and fatigue (or true corrosion fatigue) are mutually competitive and not additive as postulated by Wei and Landes. It is assumed that the crack will propagate by the fastest available mechanism at the stress intensity operative for a given crack length. The model is given in eqn [7].

$$(da/dN)_{cf} = (da/dN)_r + (da/dt) \times 1/f \quad [7]$$

where the first two terms are as in eqn [6] and  $(da/dt) 1/f$  accounts for the stress corrosion contribution.

The *process interaction model* was developed to allow interactions to occur, particularly in those systems that exhibit a degree of susceptibility to SCC.<sup>62</sup>

This model has been used to predict corrosion fatigue data for steel and aluminum in air and saline environments. The model is given in eqn [8].

$$\left(\frac{da}{dN}\right)_e = m_1 (\Delta K_{eff})^{m_2} + \int_0^{1/f} A v K_{eff}^\alpha dt \quad [8]$$

Here,  $\Delta K_{eff}$  is the effective stress intensity factor, adjusted for blunting and crack branching,  $v$  accounts for the influence of load cycle on stress corrosion rate,  $f$  is the frequency, and  $m_1$ ,  $m_2$ ,  $A$ , and  $\alpha$  are experimentally determined constants.

The ability to predict fatigue lifetime relies upon accurate information on defect size (cracks or pits), shape, and orientation with respect to the applied stress and local crack tip chemistry. Panasyuk *et al.*<sup>63</sup> proposed the use of ‘invariant diagrams’ in order to account simultaneously for the stress–strain state and the electrochemical conditions at the crack tip. They showed that for a range of alloys, including steel, Al and Ti, the pH at the crack tip differed from that of the bulk solution (NaCl, pH 6.5) by up to 5 pH points, ranging from 0.8 to 3.5. Similar studies have also been conducted by other researchers.<sup>64</sup> In contrast to measurements made at the open circuit potential, Turnbull assessed the crack tip pH and potential changes when steel was subjected to cathodic overpolarization of  $-1100$  mV (SCE). He found that the pH increased up to pH 13 and the potential moved 120 mV in the positive direction (i.e., towards the free corrosion potential). Furthermore, knowledge of the local stress–strain conditions at the crack tip is critical. Novel techniques are now being developed to obtain the geometrical shape of cracks and pits, for example, 3-D synchrotron X-ray imaging<sup>65</sup> and light-interference microscopy.<sup>66</sup> It should be noted that some of the early studies which used crack tip solution chemistry as a means to elucidate the crack tip mechanisms suffered from the fact that solutions oxidized before analysis could take place.

### 2.12.4 Variables Affecting Corrosion Fatigue

The significance of environmental effects on corrosion fatigue life has been reported by various workers. Evans and Simnad<sup>8,9</sup> in their two stage tests showed how removing the environment after a certain percentage of the expected life did not substantially increase the fatigue life. Rollins *et al.*<sup>67</sup> also concluded that the action of the corrosive environment is of

primary importance in the crack initiation stage. Duquette and Uhlig<sup>20</sup> suggested that a delay in crack initiation or early propagation, attributed to a reduction in dissolution by adopting a higher corrosion-resistant material, would lead to an improvement in the fatigue life. However, many of the earlier studies were devoted to assessing lifetime rather than quantifying crack growth. In this respect, relatively little attention has been paid to the anomalous crack growth rates of short cracks in corrosion fatigue even though they have been observed and known to exist for some time.<sup>37,68</sup> Such studies are expected to increase as environment-assisted growth of small fatigue cracks becomes increasingly recognized as an important failure mode, often dominating total life.<sup>69</sup> As discussed, most corrosion fatigue life prediction methods are dominated by the application and analysis of long crack data.<sup>70</sup> However, where defects develop from smooth 'engineering' surfaces, the application of linear elastic fracture mechanics (LEFM) becomes limited. It is therefore necessary to develop models that account for the development and growth of pits and short cracks. Furthermore, before such models can be applied, it is further necessary to consider the factors which affect the development of such small defects during the early stages.

Consideration of some of these factors is given below.

#### 2.12.4.1 Microstructure

It is widely recognized that the 'in-air' fatigue performance of a material can be significantly influenced by varying the grain size. The principal effect of grain size on short, stage I – shear, crack growth is the introduction, ahead of the crack, of physical barriers whereby the grain boundary acts as a demarcation between two grains having different slip orientations. Therefore, by introducing a large number of barriers into the system, that is, reducing the grain size, cracks are required to orientate themselves along many different planes. The effect of this is one of crack speed deceleration, and, where the stress level is below that of the fatigue limit, crack arrest.

With respect to corrosion fatigue, there is currently no direct evidence to suggest a relationship between grain size and corrosion performance, and hence corrosion fatigue resistance. However, since the environment can influence the ability of a crack to surmount the microstructural barrier, it would not be unreasonable to suggest that corrosion moderates the influence of grain size on fatigue strength.

Furthermore, given that most engineering materials contain metallurgical heterogeneities such as intermetallic particles (IMPs) and second phase precipitates, which can give rise to sites for preferential dissolution and pitting, it might sensibly be expected that a change in corrosion fatigue response will occur with changes in alloy chemistry. IMPs are particularly influential on corrosion fatigue lifetime as they lead to multisite damage and crack initiation. Furthermore, IMP can bridge individual grains, thereby reducing the influence of microstructure on crack growth. Murtaza and Akid<sup>38</sup> conducted intermittent air fatigue–corrosion fatigue loading tests and showed that the dominant microstructural feature in the corrosion fatigue behavior of a high-strength spring steel was the prior austenite grain size. Individual microstructural phases can also influence the initiation behavior, for example, duplex stainless steel consists of almost equal fractions of ferrite and austenite. However, the pitting behavior of these two phases is different with pitting being preferred in the ferrite phase.<sup>26</sup>

#### 2.12.4.2 Loading Frequency

The influence of loading frequency on 'long-crack' corrosion fatigue resistance is well documented, being attributed to time-dependent effects of corrosion which are ascribed to mass transport and electrochemical reaction rate limitations.<sup>71–73</sup>

The role of frequency on the development and growth of short fatigue cracks is, however, less well documented. Studies on smooth specimen fatigue tests<sup>42</sup> have shown that frequency influences short fatigue crack growth rates (see [Figure 12](#)). The most striking feature of this figure is that crack growth rates are enhanced at a point where the mechanical driving force is at a minimum, that is, when a crack is small and below a critical size–aspect ratio for the transfer from the stage I – shear to stage II – tensile plane. This is not an unreasonable observation as the damage process moves from a 'predominantly' time-dependent corrosion process to a mechanical, cycles-dependent fatigue mechanism. [Figure 12](#) shows that the differences in lifetime for tests at 10 and 0.01 Hz, which account for a reduction in life of 70%, occur during the growth of a defect below a size of 200  $\mu\text{m}$ . Here, it can be seen that crack growth rates, based on measurements of surface defect size with increasing number of fatigue cycles, for 0.01 Hz are around an order of magnitude higher than at 10 Hz for the same loading conditions.

**Figure 12** Influence of loading frequency on short corrosion fatigue crack growth of a low-alloy structural carbon steel in artificial seawater. Grain size approximately 10 µm. 3 Pt bend tests, stress ratio = 0.1. Reproduced from Akid, R., Wu, X. J. *Structural Materials in Marine Environments*. The Royal Society, London, UK. The Institute of Materials; 1994; pp 330–345, ISBN 1 86125 0029.

This accelerated growth at low frequency results in fatigue lifetimes of 5000 and 20 000 cycles for 0.01 and 10 Hz, respectively.

#### 2.12.4.3 Solution/Electrochemical Conditions

The corrosion resistance of a metal or alloy is normally derived from its ability or inability to form a stable passive film. The majority of passive films are based upon the formation of an oxide film and therefore the nature of the environment, that is, oxidizing or reducing, has a marked affect on film formation.

Corrosion fatigue studies<sup>7</sup> on polished carbon steel BS4360 50D showed that neutral pH chloride solutions promoted pitting, while low pH, acidic chloride solutions promoted slip-band dissolution. These differences were attributed, respectively, to local weaknesses in the surface oxide film around inclusions, hence pitting, and total dissolution of the oxide film at low pH levels, allowing access to slip bands within the grain and accelerated corrosion at these sites. The effect of these differences, in terms of fatigue behavior, is such that multiple site damage (cracking) occurred in an acidic solution, followed by coalescence of cracks and a subsequent reduction in fatigue lifetime when compared to near-neutral solution conditions.

Where solution conditions were modified to increase the thickness of the passive film,<sup>24</sup> the time

to pit formation was increased. A decrease in the propensity for local corrosion (pitting) can also be affected by modifying the solution conditions, that is, by using inhibitors. Such effects have been observed under corrosion fatigue conditions<sup>25</sup>; here, corrosion fatigue lifetimes increase on the addition of an oxidizing inhibitor, sodium nitrite ( $\text{NaNO}_2$ ). The improved CF performance is attributed to a delay in pitting and therefore an increase in time prior to crack formation.

Where electrochemical conditions are controlled to eliminate the effects of anodic dissolution, that is, cathodic polarization (CP), it is observed that the corrosion fatigue resistance is restored towards that observed for identical tests in air. It should be noted that CP may not be effective where a component or structure contains cracks that can propagate under LEFM conditions. For 'smooth' surfaces, a nonfailure condition was observed for fatigue tests carried out below the in-air fatigue limit in NaCl with CP, compared to very early failure in the absence of CP (see [Figure 13](#)).<sup>73</sup> The effect of polarization on crack growth rate requires an understanding of the crack tip electrochemistry as this controls the dissolution, repassivation, and hydrogen evolution kinetics. The trends are also subject to the nature of the material tested, and suppression of the metal dissolution reaction through the application of a negative potential is not effective for all metals. For example, applying a negative potential to Al and its alloys can lead to corrosion because the cathodic reaction promotes the formation of a high-pH solution, and as aluminum is amphoteric it can undergo dissolution at both high- and low-pH values.

#### 2.12.4.4 Surface Condition

As previously discussed, fatigue is the consequence of an extremely localized surface phenomenon. It is therefore not unreasonable that changes in the surface condition of a material have a marked effect on fatigue performance. Furthermore, it is well documented that fatigue lifetime decreases on increasing the surface roughness.<sup>74</sup> This reduction in lifetime is attributed to the presence of 'micronotches' associated with the peaks and troughs of the surface profile.

Changing the nature of the surface condition, notably stress state and microstructural condition, through the application of shot peening is a method adopted to improve fatigue performance. Here, the surface is deformed by impingement of glass or metal

**Figure 13** Influence of environment and electrochemical potential on fatigue strength; (a) fully reversed torsion loading (b) fully reversed axial loading; High-strength carbon steel ( $\sigma_y = 1100$  MPa). Reproduced from Akid, R. In *Hydrocarbon Transport and Cracking of Metals*; Turnbull, A., Ed.; The Institute of Materials, 1995; pp 50–61. Note that shear loading, as occurs in a torsion test, tends to be insensitive to hydrogen, while axial loading is more sensitive.

beads which impart a compressive residual stress in the surface layers of the metal. The interpretation of increased lifetime has, previously, been attributed solely to residual stress effects. However, it has been shown<sup>7</sup> that the resulting distortion of the microstructure also has a significant effect on the short fatigue crack growth. Figure 14 provides an example of the reduction in fatigue crack growth rate (FCGR) that occurs on the application of shot peening. Here, the FCGR under peened conditions is compared with predicted FCGR data derived from

**Figure 14** Influence of shot peening on short fatigue crack growth. (a) Air;  $\Delta\tau = 1050$  MPa,  $N_f$  (peened)  $1.4 \times 10^6$  cycles,  $N_f$  (unpeened) 114 000 cycles. (b) 0.6 M NaCl;  $\Delta\tau = 820$  MPa,  $N_f$  (peened) 270 000 cycles,  $N_f$  (unpeened) 107 000 cycles. Note solid lines represent predicted growth rates based upon a crack growth model.  $\Delta\tau_{fl} = 920$  MPa.

air tests conducted on unpeened samples at the same stress level.

Figure 14 further shows that FCG rates are decreased by an average of two orders of magnitude for both air and corrosion fatigue tests, respectively, and that despite testing in 0.6 M NaCl the fatigue crack growth rates of peened specimens are significantly lower than the predicted in-air growth rates of specimens peened to the same Almen intensity. Comparison of the fatigue lives, as given in the caption of Figure 14, shows that shot peening gives an improvement in fatigue lifetime of 13 and  $2.5\times$  for air and corrosion fatigue, respectively.

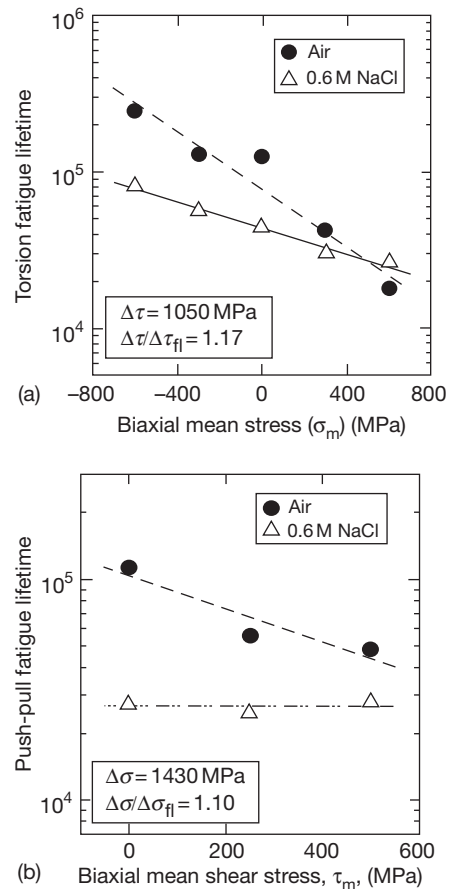

### 2.12.4.5 Stress State

Many studies have been devoted to assessing the fatigue performance of materials through the application of simple stress-life ( $S-N$ ) type testing. Such an experimental approach often adopts a simple (uniaxial) loading condition and an 'inert' (air) environment. However, engineering structures and components are often subjected to nonuniform, asymmetrical loading within environments of varying aggressivity.

The implication of adopting a simple uniaxial constant-load test condition is that a crack may propagate, in shear, and fail to transfer to a fatal mode I, tensile crack. Where a multiaxial loading condition applies, both the maximum shear strain and strain normal to the maximum shear plane govern whether or not a crack will arrest (nonpropagating crack) or grow to failure.<sup>75</sup>

Recent multiaxial 'in-air' fatigue tests<sup>75</sup> have shown that, for mixed tension-torsion testing, the application of a static tensile stress, superimposed on a cyclic torsional load, significantly reduces the fatigue lifetime. Conversely, a compressive stress increases the lifetime, such effects being attributed to the relationship of the orientation of crack and stress state, and its relationship to the microstructure. Corrosion fatigue tests conducted under identical conditions<sup>75</sup> showed that the environment eliminates the effects of the stress state and the early stages of damage (see Figure 15(a)), are controlled by the environment, via a pitting mechanism, with fatigue lifetime becoming independent of biaxial stress state (see Figure 15(b)). As the crack size increases, environmental effects are more dominant for negative biaxial stress states; while at positive biaxial stress states, the mechanics dominate crack growth.

Additional corrosion fatigue studies concerned with block loading sequences, that is, damage accumulation (DA) loading<sup>76</sup> have also shown that corrosion fatigue lifetime is primarily governed by the ability to develop a small defect, that is, a pit, which transforms to a stage I, tensile crack. In this respect, there are two distinct regimes of damage; notably, a time-dependent corrosion regime, governed principally by solution chemistry, followed by a cycle dependent fatigue regime, governed by the magnitude of stress and mode of loading. Where appropriate conditions apply, that is, crack size and stress state,<sup>73</sup> the ability to generate hydrogen capable of being adsorbed into the metal matrix ahead of the

**Figure 15** Influence of biaxial stress state on corrosion fatigue lifetime, (a) fully reversed torsion with tensile and compression loading, (b) fully reversed axial loading with static torsion loading. High-strength spring steel, loading frequency of 5 Hz. Reproduced from Akid, R.; Zhang, W. In *Engineering Against Fatigue*; Beynon, J. H., Brown, M. W., Lindley, T. C., Smith, R. A., Tompkins, B., Eds.; A. A. Balkema: Rotterdam, Brookfield, 1999.

crack tip will also play a part in controlling damage and hence lifetime.

## 2.12.5 Corrosion Fatigue of Specific Alloys

### 2.12.5.1 Ferrous Alloys

Carbon steel is the highest tonnage alloy used within the engineering sector. It is, however, an alloy with limited corrosion resistance and therefore its application where both stress and corrosion may operate in combination needs careful consideration. In an attempt to extend the service life of steel

structures, carbon steels are often subjected to cathodic protection (CP), for example, in oil and gas exploration applications. In some cases, these materials are also painted to reduce the current demand from the CP system. CP reduces the operating electrode potential of the steel to typically more negative than  $-850$  mV (vs. Ag/AgCl), that is, below its natural open circuit potential. Where CP is used, careful material selection is required in order to prevent any possible hydrogen embrittlement (HE) problems. Typically, steels having yield strengths of less than about 700 MPa are considered to be immune from HE, although this is affected by the loading conditions and hydrogen concentration.

Given that chloride is very aggressive towards ferrous based materials and that many structures are located either offshore or in coastal regions, it is not surprising that many studies have been devoted to the corrosion fatigue behavior of steels in seawater or artificial seawater environments.

The 1970 and early 1980s saw significant research activity devoted to the corrosion fatigue resistance of offshore structural steels and pressure vessel steels<sup>55,57,61,77</sup> and more latterly to steels having refined microstructures such as roller quench temper (RTP) grades.<sup>33,42</sup>

Barsom<sup>78,79</sup> demonstrated the effects of frequency and cyclic waveform, identifying crack growth regimes above and below the threshold stress intensity factor for stress corrosion cracking. He observed that low loading rates (negative sawtooth) were more detrimental than high loading rates (positive sawtooth) and attributed this to the time available for corrosion and crack extension during the loading part of the cycle. Scott<sup>80</sup> in a separate study illustrated the effects of stress ratio on crack growth rate and cathodic protection on the evolution of a SCC plateau region. The plateau region exhibits an independence of crack growth on the stress intensity value, suggesting that a rate-limiting process is operative. In this case, the rate determining step was attributed to hydrogen evolution and transport at the crack tip.

The specific mechanism(s) leading to corrosion fatigue remain(s) in debate. Gangloff<sup>81</sup> summarized the possible processes that lead to enhanced fatigue crack growth under CF loading suggesting the following mechanisms may be involved: hydrogen embrittlement, film rupture, dissolution, and repassivation; enhanced localized plasticity and interactions of dislocations with surface dissolution, films, or adsorbed atoms.

The dominant mechanism is controlled by both the nature of the materials and the electrochemical conditions at the crack tip. Metals with high yield strength are susceptible to HE unless the local crack tip pH values are alkaline which then lead to charge transfer controlled dissolution process governing crack growth. Wei<sup>82</sup> showed, for an X-70 pipeline steel in a carbonate–bicarbonate solution at pH = 9, that changing cyclic frequency and temperature led to changes in fatigue crack growth rate, indicating the important role of dissolution kinetics.

Environment also has a role to play in the cracking of a high-strength low-alloy (HSLA) steel. Recent work has been conducted by Ritter<sup>83</sup> who studied the CF crack growth behavior of different RPV steels over a wide range of environmental (temperature, electrochemical potential, dissolved oxygen,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$ ), loading ( $\Delta K$ ,  $R$ ) and material (S, MnS, microstructure) parameters in oxygenated or hydrogenated high temperature water, applying cyclic load tests with precracked fracture mechanics specimens. The application of hydrogenated water was always found to result in a reduction of low-frequency CF crack growth rates (CGRs) by at least one order of magnitude with respect to oxygenated conditions. A few hours after changing from oxidizing to reducing conditions, the CGRs dropped below the corresponding ASME crack growth curves.

Ford also showed the importance of passive film rupture and transient anodic dissolution for pressure vessel steels for high temperature pure-water environments.<sup>84</sup> Faraday's law was employed to determine the metal loss during active dissolution, the total metal loss being an integral of the current–time transient response of the metal. The contribution from anodic dissolution was shown to be strain rate and cyclic frequency dependent.

The microstructure of the material has also been shown to play an important role in the resistance to CF cracking. Using a superposition model for a high-purity FeCrNi alloy, Gao<sup>85</sup> assessed the role of microstructure in hydrogen-assisted corrosion fatigue crack growth. He concluded that the environmentally assisted crack growth rate in  $\alpha$ -martensite was only twice as high as that in vacuum, while the rate through the austenite grain and twin boundaries is more than one order of magnitude faster. He suggested that the results indicated that strain-induced  $\alpha$ -martensite formation is not a principal contributor to the environmental enhancement of corrosion fatigue crack growth and is not necessary for hydrogen embrittlement.

Mechanical factors also influence the nature of the cracking mechanism. Wu<sup>86</sup> studied the influence of strain rate on the low-cycle fatigue resistance of ASTM A 533B low-alloy pressure vessel steel in simulated BWR water. At strain rates above  $0.001\% \text{ s}^{-1}$ , the fatigue life decreased almost linearly with decrease in the strain rate on a log–log plot with environmental effects tended to become saturated at strain rates below  $0.001\% \text{ s}^{-1}$ . It was suggested that the change in strain rate leads to a change in the environment-assisted cracking (EAC) mechanism from hydrogen-induced cracking to a film-rupture-slip-dissolution-controlled process, mainly influencing the rupture rate of oxide film at the crack tip, and mass transfer and local electrochemistry processes in the system. It was also proposed that MnS inclusions play an important role in fatigue crack initiation and propagation where dissolution of the inclusions in the high temperature water environment results in  $\text{H}_2\text{S}$  formation which may enhance the hydrogen-induced cracking process.

While there is general agreement on the role of hydrogen in EAC for high- and low-strength steels in aqueous low temperature environments, it remains debated as to the exact mechanisms operative at high temperatures.

### 2.12.5.2 Stainless Steels

The susceptibility of stainless steels to CF is dependent upon the steel grade, notably ferritic, martensitic, austenitic, or duplex, the strength level, and environmental conditions.

Stainless steels are renowned for their superior corrosion resistance when compared to low-alloy carbon steels. However, where the prevailing environmental conditions lead to pitting corrosion the fatigue strength of the stainless steel grades is often not appreciably greater than the nonalloyed steel counterparts, assuming equivalent mechanical strength levels.

An example of the reductions in fatigue strength of a range of stainless steel grades is given in Table 3. The data represent rotating bending test results (stress ratio equal to  $-1$ ) in air and for samples moistened in 3% NaCl solution.

It can be seen from Table 3 that there is a significant reduction in endurance limit of the ferritic and martensitic grades, being some 30–50% of the in-air limit. Increasing the corrosion resistance to an austenitic grade improves the CF resistance, while a combination of high mechanical strength and good

**Table 3** Rotating bending fatigue test results for different stainless steel grades

Steel grade	Yield strength (0.2%, MPa)	Air fatigue limit (MPa)	CF endurance limit (MPa)
410 (martensitic)	440	340	130
12% Cr Mo (ferritic)	55	415	140
Precipitation-hardened martensitic	1060	550	230
304 (austenitic)	326	260	230
316 (austenitic)	223	270	260
Duplex	475	450	355

Reproduced from Shrier, 3rd ed.

corrosion resistance can be obtained by moving to a duplex grade.

The nature of the CF mechanism operative in stainless steels remains in debate. While it is recognized that active dissolution takes place when the passive film is broken, it is not entirely clear whether hydrogen, generated as a result of metal ion hydrolysis, further contributes to the crack propagation rate.

Using long focal length video optical microscopy to measure hydrogen bubble diameters at the crack mouth, Olive<sup>87</sup> conducted *in situ* monitoring of natural cracks. A boundary condition of the hydrogen evolution inside a crack was obtained and, by considering the electrochemical reactions occurring inside a crack, a minimum volume of metal dissolved per cycle at the crack tip was proposed. No comment was made as to any synergistic effect of hydrogen adsorption and any consequential changes in embrittlement ahead of the crack tip.

Magnin<sup>88</sup> studied the corrosion fatigue damage mechanisms leading to crack initiation in high-purity ferritic stainless steels (Fe–26Cr–1Mo wt%) in a 3.5% NaCl solution at 300 K and an imposed anodic corrosion potential. Particular attention was paid to the influence of strain rate on both the plastic deformation mechanisms and dissolution characteristics, which govern the crack initiation process. In summary, it was found that:

- At high strain rates (about  $10^{-2} \text{ s}^{-1}$ ), pencil glide induces strain localization at grain boundaries; dissolution is localized at grain boundaries; crack initiation is intergranular, and lifetimes are reduced in comparison with those in air.

- At intermediate strain rates (about  $10^{-3} \text{ s}^{-1}$ ), dissolution is entirely localized at grain boundaries because of pencil glide; crack initiation is intergranular, and fatigue lifetimes are shorter than at high strain rates.
- At low strain rates (less than  $10^{-4} \text{ s}^{-1}$ ), the amount of dissolution is lower than the critical value for corrosion fatigue damage; crack initiation is transgranular, and fatigue lifetimes are similar in air and in the corrosive solution.

Nyström<sup>89</sup> presented a study showing the effects of heat treatment and resulting changes in microstructural condition on the low-cycle CF resistance of 25% ferrite and 75% austenite duplex stainless steel. He and his coworker pointed out a major drawback of duplex stainless steel, being that of the susceptibility of the ferritic phase to 475 °C embrittlement; potentially limiting the use of duplex stainless steel to temperatures below 250 °C. The mechanical properties of duplex stainless steel were compared to those of an austenitic stainless steel. The results indicate that the fatigue properties of the duplex grade are little affected by annealing at 475 °C for 100 h. In addition, after annealing, the impact toughness remained high at 130 J. The austenitic grade has the same nominal fatigue crack growth threshold as the duplex grade; however, the effective crack growth threshold, related to the (intrinsic) internal resistance of the material to crack extension and the (extrinsic) level of crack closure, of the duplex grade is higher than that of the austenitic grade.

### 2.12.5.3 Aluminum Alloys

Aluminum alloys may be classed as either heat-treatable or nonheat-treatable, providing a range of alloys with different properties. The main industrial alloys include the Al–Cu; 2xxx series, Al–Zn–Mg 5xxx series, and Al–Mg–Zn 7xxx series. Heat treatment of these alloys produces precipitation hardening which can be controlled to alter the tensile and yield strength. This in turn affects the sensitivity of the alloys to environment sensitive cracking and localized corrosion. Like the high-strength steels, the high-strength 2xxx and 7xxx series have reduced resistance to stress corrosion cracking, hydrogen embrittlement, and corrosion fatigue. Furthermore, it has been shown that small fatigue cracks grow faster than, and below the thresholds of, long cracks in both active (air at 60% relative humidity) and inert (vacuum and dry nitrogen) environments.<sup>90</sup>

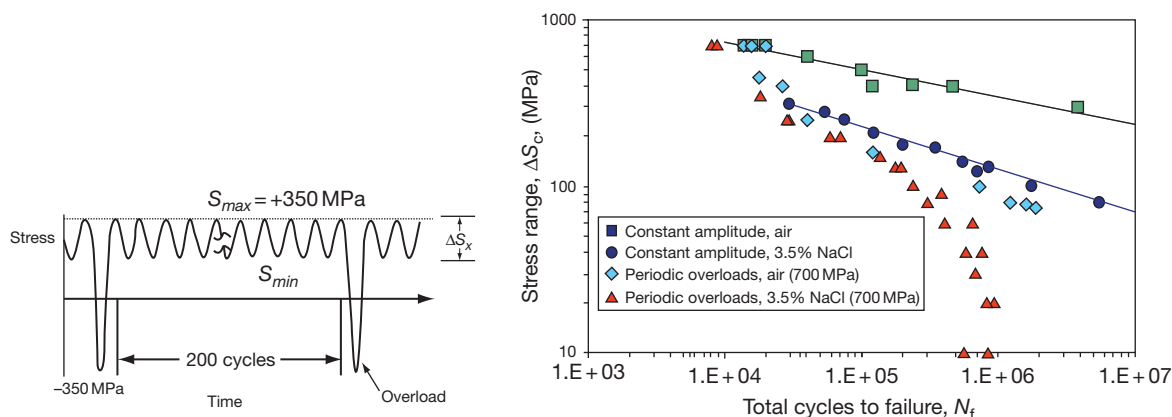

Of major interest to the aerospace industry is the role of intermetallic precipitates in the development of pitting and subsequent crack initiation. Inclusions may be either anodic or cathodic with respect to the surrounding matrix. In either case, a microgalvanic cell is established which leads to local corrosion. Pit-like features act as stress concentration sites where crack initiation can take place. Metal ion hydrolysis leads to the formation of a low-pH solution within the pit. In turn, this can lead to hydrogen embrittlement or advancement of the crack via metal dissolution. The heat-treatable alloys tend to be more susceptible to EAC because the heat-treatment ageing process has a marked influence on the resulting microstructure of the material. Kumai *et al.*<sup>91</sup> showed that ageing of the Al–Li and Al–Li–Cu alloys can lead to precipitate free zones along the grain boundaries, affecting the corrosion resistance of the alloys. In another study, it was shown that where the addition of Li promotes the formation of a passive film, the corrosion resistance of the alloy was increased.<sup>92</sup>

Ro *et al.*<sup>93</sup> showed that the LEFM-regime fatigue crack growth kinetics for an Al–Cu–Mg/Li alloy were dependent not only on  $\Delta K$  and stress ratio,  $R$  but also on the factor  $P_{\text{H}_2\text{O}}/f$ , namely, the ratio of water vapor pressure to cyclic frequency. It was observed that the water vapor exposure dependence of  $da/dN$  exhibits four regimes of behavior and that there is no exposure effect below a threshold  $P_{\text{H}_2\text{O}}/f$  of 0.01 Pa s. At moderate water vapor exposures (0.02–2 Pa s), impeded molecular flow governs  $da/dN$ , whereas hydrogen diffusion rate limitation and surface reaction saturation intervene to reduce the  $da/dN$  dependence on  $P_{\text{H}_2\text{O}}/f$  at higher exposures. A plateau growth rate response was observed above 100–1000 Pa s.

The importance of mechanical loading effects on AA7075–T651, notably periodic overloads, was shown by Chlistovsky *et al.*<sup>94</sup> for smooth specimens. They concluded that the effect of periodic overloads was limited at high-cyclic amplitude loads ( $\Delta S$  values) between 100 and 450 MPa, but below this value fatigue life was significantly reduced (see Figure 16).

It was concluded that the reduction was due to premature crack initiation from surface pitting.

Further clarification of the role of overloads may be gained by considering their role in the development of short fatigue crack growth. Akid's study on damage accumulation under corrosion fatigue conditions<sup>76</sup> showed that cracks grow faster when subject to a low–high stress sequence in comparison

**Figure 16** Periodic overload sequence and fatigue life data for 7075-T651 aluminum alloy in air, and simulated seawater. Reproduced from Chlistovsky, R. M.; Heffernan, P. J.; DuQuesnay, D. L. *Int. J. Fatigue* **2007**, 29, 1941–1949.

to that of a high–low stress sequence. This observation was rationalized on the basis that during low stress cycling (below the in-air fatigue limit), the corrosion component is more damaging than the fatigue component. Where tests are conducted at an initial high stress (above the in-air fatigue limit), the contribution from corrosion is small compared to that from fatigue. In the case of Chlistovsky's study, the maximum effect of overloads was seen for corrosion fatigue below the in-air fatigue limit. Here, corrosion can progress the defect up to the microstructural barrier where, in principle, a single overload can propagate the defect beyond the barrier. When the stress level is restored to below the in-air fatigue limit, the crack progresses assisted by corrosion up to the next major microstructural barrier.

The presence of preexisting corrosion pits on the fatigue behavior of notched 7075-T7351 was studied by Pao *et al.*<sup>95</sup> Corrosion damage was produced by immersion in 3.5 wt% NaCl solution for 336 h. They observed that pitting shortens the fatigue crack initiation life in air by a factor of two to three and decreases the fatigue crack initiation threshold,  $(\Delta K/\sqrt{\rho})_{th}$ , by about 50%, where  $\rho$  is the notch root radius. Fatigue cracks in polished blunt-notched specimens often initiated from large constituent particles.

#### 2.12.5.4 Titanium Alloys

Titanium has found important uses in a range of sectors, including aerospace, offshore and biomedical because of its good fatigue strength, low specific weight, and good corrosion resistance. Its high corrosion resistance is attributed to the instantaneous

formation of an inert Ti oxide surface layer. However, low wear resistance and the poor tribological properties of titanium and its alloys are of concern. This is of particular importance in the case of metal release within the body and potential poor performance where there is a combination of fretting, fatigue, and a corrosive environment that is not conducive to the repassivation of the alloy.

Titanium alloys can be classified into three main groups depending upon the microstructural condition of the alloy, namely,  $\alpha$ ,  $\alpha/\beta$ , or metastable  $\beta$ . The microstructural condition and state of alloying provide Ti alloys with a wide range of mechanical properties, notably yield strengths up to 1400 MPa. This in turn gives a range of fatigue strength for these alloys.

Ti alloys have been shown to be susceptible to both corrosion fatigue and stress corrosion cracking.<sup>96</sup> As with other alloys that show this combination, there can be a marked increase in crack growth rates when the loading–defect size combination leads to stress intensity values above  $K_{ISCC}$ . These were obtained using precracked specimens, and the increase in crack growth rate has been attributed to hydrogen embrittlement. Shipilov<sup>97</sup> reported that, depending upon the nature of the environment used, cathodic and anodic polarization excursions may or may not accelerate or retard crack growth in VT20 and TS6 alloys. It is of interest to note that the effects of cathodic polarization, notably retardation in crack growth, can depend upon the nature of the material and the size of the crack; for these Ti alloys, crack growth is retarded, while for high strength steel, as shown in Figure 13, the development of pits and subsequent short fatigue cracks was retarded.

Goa showed that the fatigue response of Ti alloys in water vapor is identical to that of Al alloys<sup>98</sup> where crack growth rates increased with increasing water vapor pressure up to the saturation pressure. Frequency effects were also studied, and it was observed that crack growth rates increased with decreasing frequency and reached a maximum that depended upon  $\Delta K$  after which growth rates decreased to those comparable with rates observed in vacuum or other inert environments.

With the recent increase in the use of Ti alloys for prosthetic devices, there has been a significant amount of research on the fatigue and corrosion behavior of alloys, such as Ti4V6Al, in actual and simulated body environments. Leinebach *et al.*<sup>99</sup> investigated the cyclic deformation behavior of the binary titanium alloys Ti-6Al-4V and Ti-6Al-7Nb under axial stress-controlled constant amplitude and increasing load tests as well as in loading sequences based on gait patterns from human walking. They concluded that slight differences in the materials' microstructures result in differences of the fatigue and cyclic deformation behavior. In comparison to the results of constant loading rate tests, the standard walking gait pattern tests revealed shorter lifetimes for identical maximum stresses. It was also noted that the fatigue strength was also decreased by corundum grit blasting, that is, increase in surface roughness.

Papakyriacou *et al.* similarly conducted long-term corrosion fatigue tests comparing potential skeletal implant materials, namely cold-worked c.p. niobium and commercially pure (c.p.) tantalum with titanium and Ti-6Al-7Nb alloy.<sup>100</sup> Constant amplitude fatigue experiments (*S-N* curves) were performed at an ultrasonic frequency of 20 kHz with two different surface structures (ground surface and blasted and shot-peened surface) in ambient air and in a corrosive fluid similar to the body fluid in the oral cavity. They recorded a decrease in fatigue limit of 5–20% at 20 million cycles and a detrimental effect of surface finish on the Ti alloys compared to the Nb and Ta candidate materials. However, while this study shows that the Ti alloys can suffer from corrosion fatigue, it should be noted that the extreme high-cyclic test frequency used is not representative of typical implant loading conditions. Given that CF is more pronounced at low test frequencies, the results obtained in this study are likely to be conservative.

Titanium alloys are also gaining increased use in aerospace applications and are used in aircraft gas turbine engine blades and discs as well as in highly stressed components such as forged wing structures

and landing gear components. In this type of application, there is also the possibility that an additional damage mechanism may be operative, notably that of fretting. Fretting is the surface damage that occurs when contacting surfaces between mating bodies experience an oscillatory motion of small amplitude. The combination of this motion between two surfaces that are subject to loading is termed 'fretting fatigue.' Fretting fatigue increases the tensile and shear stresses at the contact surface producing surface defects which can act as stress concentration sites. Lietch *et al.*<sup>101</sup> investigated the fretting fatigue behavior of Ti-6Al-4V in ambient laboratory air and under a controlled environment consisting of synthetic seawater. Tests were performed over a wide range of the maximum axial stresses, ranging from 380 to 760 MPa, to examine both low- and high-cycle fatigue regimes. They concluded that seawater had a deleterious effect on fretting fatigue life in the low-cycle fatigue regime but improved the life in the high-cycle fatigue regime. *S-N* data showed marginal differences between the fatigue limit in air and in seawater, although there were limited data points and a high degree of scatter. The results of Leitch (Ti alloy) differ from those obtained by Shaluf,<sup>102</sup> working on a high-strength steel, in which Shaluf showed that fretting under corrosion fatigue conditions reduced the fatigue life at all stress levels.

## 2.12.6 Prevention of Corrosion Fatigue

Prevention of corrosion fatigue relies upon simple strategies such as lowering the fatigue stress level, adopting more corrosion-resistant alloys or eliminating the corrosion activity, in this case, by either forming a barrier on the surface of the substrate or by applying a negative electrode potential to suppress the anodic dissolution reaction. The former of these strategies, notably reducing the stress, is by far the easiest approach; however, this will reduce the operating loads that can be applied to a given component or structure. Consequently, this approach is rarely used.

### 2.12.6.1 Prevention by Barrier Coatings and Surface Treatments

Historically, barrier coatings have been used to protect substrates from reacting with the environment. Metallic and nonmetallic coatings, for example, hot-

dip galvanizing and paints offer differing benefits such as cost and ease of applicability, wear resistance, increased corrosion resistance, etc. However, there have been mixed benefits of applying coatings with respect to the enhancement of fatigue lifetime. The principle philosophy behind this approach is that the coating system will prevent contact of the corrosive media, and hence the material will essentially act as if it was under stress within a benign environment. This does, however, rely on the barrier remaining intact and not suffering failure from fatigue itself. Where coating breakdown does occur, there are several possible outcomes. With nonmetallic coatings, localized corrosion may take place at the coating failure site, thereby leading to a local stress concentration. In the case of a metallic coating, it is possible that the coating acts in a sacrificial manner and protects the underlying substrate, for example, Zn and Al coatings on steel. However, it should be pointed out that when the electrochemical potential of a coating is significantly lower than that of the substrate these types of coatings can liberate hydrogen during the dissolution process. This in turn can be adsorbed into the metal and, subject to the nature of the substrate, lead to hydrogen embrittlement. Alternatively, where a metallic coating is noble to the underlying substrate, failure of the coating can lead to accelerated localized corrosion due to galvanic action between the two dissimilar metals and subsequent crack initiation. A further consideration is that of crack initiation in the coating. This is particularly relevant for hard coatings that lack ductility, for example, chromium and nickel. The effects on fatigue life of crack initiation can be compounded if the coating is noble to the substrate, for example, Ni on steel. The initiation of a crack can lead to solution ingress to the substrate and the formation of a local galvanic cell whereby the underlying steel substrate is attacked locally leading to pitting and the formation of a stress concentrating feature.

As previously discussed, both shot peening and surface coatings can influence the fatigue performance of a material. Asquith *et al.*<sup>103</sup> assessed the combination of shot peening and a plasma electrolytic oxidation (PEO) treatment on the corrosion performance of a 2024 aluminum alloy. Shot peening was found to decrease the corrosion resistance, as assessed by electrochemical impedance spectroscopy, while shot peening followed by PEO improved the corrosion resistance. Marin de Camargo *et al.*<sup>104</sup> assessed the effects of coating residual stresses on the fatigue performance of a 7070 Al alloy. They

concluded that a 17% Co thermally sprayed coating improved the axial fatigue resistance, while different anodizing treatments decreased fatigue resistance. Shot peening of anodized layers improved the fatigue life over that of nonshot-peened surfaces.

Alternative surface treatments that influence the surface metallurgy, and hence the localized corrosion performance have also been investigated. Wu *et al.*<sup>105</sup> evaluated the effects of laser surface melting (in air and in N<sub>2</sub>), using an excimer laser, to improve the resistance to fatigue cracking of aluminum alloy 6013 induced by pitting corrosion. Analysis of the electrochemical impedance measurements showed that the laser-formed AlN and/or Al<sub>2</sub>O<sub>3</sub> layer can greatly reduce the rate of electrochemical reaction. The corrosion fatigue lives of the air-treated and the N<sub>2</sub>-treated specimens were found to increase by two and four times compared to the untreated specimens. Furthermore, the corrosion current for the laser-treated specimens (measured during the fatigue test) was considerably lower than that for the untreated specimens, the improvement in lifetime being considered to be due to the excellent initiation resistance to pitting corrosion of the laser-treated specimens.

### **2.12.6.2 Prevention by Cathodic Protection**

Cathodic protection operates on the principle of lowering the potential of the metal to a value below its normal open-circuit potential. This topic is covered elsewhere in this book and therefore will not be discussed in detail. However, its relevance to corrosion fatigue is that the cathodic partial reaction can lead to the generation of atomic hydrogen which in turn can give rise to hydrogen embrittlement of high-strength alloys. A typical rule of thumb when protecting steel is to prevent the potential becoming more negative than  $-900\text{ mV (Ag/AgCl)}$  and use alloys that have a yield strength less than 700 MPa.

## **2.12.7 Summary**

This chapter has considered the role of corrosion on the fatigue performance of a range of engineering materials. Specific attention has been given to discussing the early stages of corrosion fatigue for damage emanating at nominally ‘defect’ free surfaces. This stage has traditionally been referred to as ‘initiation.’

Corrosion fatigue damage of alloys in aggressive solutions progresses through several stages including surface film breakdown, localized dissolution/pitting at slip bands or nonmetallic inclusion, transfer from corrosion-dominated growth to fatigue cycles-dependent cracking and subsequent transfer to, environmentally-assisted microstructurally independent cracking in a 'continuum mechanics' growth regime.

A number of factors have been shown to influence individual stages of the corrosion fatigue process; including atmospheric or solution conditions, electrochemical potential, applied stress state, loading frequency, surface stress state and microstructural condition.

The 'free corrosion' fatigue lifetime of 'smooth' specimens is considered to be dominated by the ability to grow a defect, that is, a pit or crack, beyond crack-arresting microstructural barriers inherent within the material. Given the appropriate solution and loading conditions, this early dissolution dominated regime, along with the transition of a pit to a crack, has a major effect on the fatigue lifetime of a material. The major factors, which are known to control smooth specimen lifetime under in-air fatigue loading, notably microstructure, loading mode and biaxial stress state, play a less significant role under corrosion fatigue conditions. Test frequency, however, is a dominant factor in controlling smooth specimen corrosion fatigue lifetime. Overall it is considered that the environment, in particular, anodic dissolution plays a major part in controlling fatigue lifetime for stress levels below the in-air fatigue limit.

In the case of corrosion fatigue of structures containing preexisting defects, the most important factors include solution chemistry, test frequency, load ratio, and crack tip stress intensity. Of particular concern for cracked components is hydrogen embrittlement, especially when high-strength alloys are employed in conjunction with cathodic protection. A similar problem can arise if these materials are cleaned in acidic solutions or electroplated.

The nature of the surface is especially important, as corrosion fatigue is predominantly a surface phenomenon. Controlling the surface residual stress state, surface roughness, electrode potential and applying coatings have a marked effect on performance. Coatings, in particular, can be a low-cost strategy to exclude contact between the substrate and the environment and, in effect, simulate an inert environment for the material. Caution is required where the coating is brittle and noble to the substrate as this may accelerate damage and decrease fatigue lifetime.

### Symbols

$E_{\text{corr}}$	Free corrosion potential (V)
$E_{\text{intact}}$	Free corrosion potential of an intact polymer coated metal (V)
$pK_a$	Acid dissociation constant
$x_{\text{del}}$	Delamination distance ( $\mu\text{m}$ )
$t_{\text{del}}$	Delamination time since electrolyte contact (min)
$t_i$	Delamination initiation period (min)
$\phi_{\text{sc}}$	Strontium chromate pigment volume fraction
$\phi_{\text{pa}}$	Polyaniline pigment volume fraction

### 2.14.1 Introduction

Corrosion-driven organic coating delamination, in which the more-or-less intact coating becomes physically separated from the underlying substrate, is a key failure process affecting painted, lacquered and otherwise organically coated metal products, and the subject has been reviewed elsewhere.<sup>1–6</sup> Here, we will attempt a brief overview and update of the topic. In so doing, we will concentrate on two processes of corrosion-driven coating delamination, which have been extensively characterized and have reasonably well-defined mechanisms, namely *cathodic delamination* and *filiform corrosion* (FFC). Both of these phenomena tend to propagate from preexisting breaks or penetrative defects in the organic coating, which act to admit species from an external electrolyte. In the case of cathodic delamination, separation of the organic coating is linked to the cathodic reaction in a localized corrosion cell. In the case of FFC, separation of the organic coating is frequently linked to the anodic reaction. As such, cathodic delamination and FFC are closely related to the phenomena of cathodic blistering and anodic blistering.<sup>7–10</sup> It is not our intention to further describe or discuss blistering as a separate phenomenon. Neither is it our intention to describe or discuss the processes by which ions from an external electrolyte diffuse or migrate through a nominally intact organic coating.<sup>11–13</sup> We will restrict our comments to situations in which electrolyte species have penetrated through a penetrating defect and describe the

corrosion processes that then ensue at the defect and beneath the organic coating.

### 2.14.2 Cathodic Delamination

One of the most common and therefore economically important mechanisms of coating delamination on iron (mild steel) and zinc (galvanized) surfaces involves so-called cathodic delamination.<sup>1,3,4,14–24</sup> This process can occur wherever the metallic substrate becomes exposed to scratches or cut edges during manufacturing or through in-service damage. Numerous studies have indicated that when iron or zinc substrates are exposed to aqueous electrolyte through penetrative defects in an organic coating, a *cathodic delamination cell* may become established. In this cell, a thin layer of electrolyte, which penetrates beneath a region of already delaminated coating, acts to couple anodic metal dissolution occurring at the coating defect to cathodic oxygen reduction occurring at the site of coating disbondment. An alkaline environment forms at the cathode, and suggested mechanisms of coating disbondment include the dissolution of an amphoteric metal oxide film at the metal–coating interface (in the case of zinc), base-catalyzed polymer degradation, base-catalyzed hydrolysis of interfacial bonds, and attack on the polymer by hydrogen peroxide and other reactive intermediates in cathodic oxygen reduction.

Koehler showed that cathodic delamination (which he called halo detachment) occurred only when group I (alkali metal) cations were available to act as counter ions to cathodically generated  $\text{OH}^-$ .<sup>14</sup> This is because only group I cations possess the hydrolytic stability and solubility at high pH necessary to support a strongly alkaline electrolyte. Ammonium salts do not produce cathodic delamination because the ammonium cation ( $\text{NH}_4^+$ ,  $\text{p}K_a$  9.3) decomposes to ammonia ( $\text{NH}_3$ ) at high pH.<sup>14,21</sup> Group II (alkaline earth) salts do not produce cathodic delamination because of the limited solubility of group II hydroxides.<sup>14,21,25</sup> When group I cations are present, a very high local pH can be produced. In a work involving cellulose nitrate coatings on iron, Ritter and Kruger measured a pH approaching 14 beneath the delaminated coating for a natural corrosion situation with 0.05 M NaCl.<sup>26</sup> However, from their accompanying ellipsometric measurements, it seems most likely that actual delamination took place when the pH was  $\sim 11$ .

Two possible routes exist for species undergoing transport to the cathodic site, (vertically) through the coating or (horizontally) along the polymer–substrate interface. Leidheiser *et al.* showed that water transport occurs through the coating.<sup>1,18</sup> They also showed that oxygen transport occurs predominantly through the coating in nonpigmented coatings, with a minor contribution from interfacial transport. Water and oxygen transport are not usually the rate controlling processes in cathodic delamination.<sup>1,18</sup> However, in pigmented coatings, where the pigment hinders through-coating diffusion, interfacial oxygen transport can become important and rate limiting.<sup>21</sup> Leidheiser identified a linear relationship between cation diffusion coefficient in aqueous solution and cathodic delamination rate for a range of group I chloride salts. This suggested that cation transport occurred principally through migration along the interface. However, because delamination rates also showed a strong dependence on film thickness, through-coating transport could not be ruled out.<sup>27</sup> The notion of interfacial cation migration was further supported by the work of Castle and Watts.<sup>28</sup> They used electron probe micro-analysis (EPMA) to show that  $\text{Na}^+$  cations superficially penetrated the delaminated coating from both bulk solution and the interface, but detected no  $\text{Na}^+$  within the interior of the coating, thus ruling out the possibility of through-coating transport. They also found that delamination rate decreased with increasing substrate surface roughness and, therefore, increasing tortuosity of the coating–substrate interface. This finding is also consistent with the notion of interfacial cation migration as the rate controlling step.

Probably the most systematic recent work on the cathodic delamination of organic coatings from iron<sup>29–31</sup> and the zinc surface of electrogalvanized steel<sup>32–34</sup> was carried out by Stratmann *et al.* in a series of experiments designed to preclude the possibility of through-coating cation transport. They prepared their samples and used a scanning Kelvin probe (SKP) apparatus in a configuration similar to that shown in Figure 1. Under these circumstances, a cathodic delamination cell becomes established, and a thin layer of electrolyte ingresses beneath the delaminated coating in the manner shown schematically in the lower part of Figure 2. The SKP is calibrated to record the local free corrosion potential ( $E_{\text{corr}}$ ) as a function of distance ( $x$ ) from the edge of the organic coating defect. As delamination proceeds,  $E_{\text{corr}}(x)$  profiles develop as shown schematically in the upper part of Figure 2. These may be approximately resolved into four characteristic regions as follows:

**Figure 1** Schematic diagram showing (a) sample preparation and (b) experimental procedure for a typical delamination experiment.

**Figure 2** Schematic representation of the corrosion-driven delamination cell showing correspondence with various regions of the time-dependent  $E_{\text{corr}}(x)$  profile.

1. The region immediately next to the defect where  $E_{\text{corr}}$  is low and ultimately becomes similar to that of the freely corroding metal.
2. A region of  $E_{\text{corr}}$  gradient linking region (I) with region (III) below and resulting, at least in part, from ohmic resistance to ionic current flow in the thin under-coating electrolyte layer.
3. A region of sharp transition in  $E_{\text{corr}}$  corresponding to the cathodic delamination front where coating disbondment takes place.
4. A region of as yet undelaminated polymer where oxygen can diffuse to the metal surface but electrolyte is not present and metal cannot

corrode. Here,  $E_{\text{corr}}$  (or the intact potential  $E_{\text{intact}}$ ) is high.

Stratmann's technique is robust and reproducible. Figure 3 shows SKP derived  $E_{\text{corr}}(x)$  profiles obtained, by ourselves, from unpigmented 30  $\mu\text{m}$  polyvinyl butyral (PVB) coatings on the zinc surface of (hot dip) galvanized steel (HDG), undergoing cathodic delamination with 5% aqueous NaCl in contact with the coating defect. The location of the delamination front can be determined from the point of maximum  $dE_{\text{corr}}(x)/dx$  gradient.<sup>30</sup> The distance ( $x_{\text{del}}$ ) over which delamination has occurred is related to the time since electrolyte contact ( $t_{\text{del}}$ ) by,

$$x_{\text{del}} = k_d(t_{\text{del}} - t_i)^{1/2} \quad [1]$$

where  $k_d$  is a parabolic rate constant and  $t_i$  is the initiation period – that is the time delay between electrolyte contact and the onset of cathodic delamination. Initially, the substrate–coating interface is intact, and anions and cation ingress simultaneously by diffusion. Because the coating is fully hydrated at the time of electrolyte contact,  $t_i$  was taken to be the time required for interfacial ionic concentration to rise to a level capable of supporting cathodic  $\text{O}_2$  reduction.<sup>30</sup> Below a concentration threshold of 0.05 M inside the defect, delamination was not observed, implying that a minimum interfacial ionic

**Figure 3** Time-dependent  $E_{\text{corr}}$  (versus standard hydrogen electrode, SHE) as a function of distance ( $x$ ) from the defect edge profiles recorded for unpigmented 30  $\mu\text{m}$  polyvinyl butyral (PVB) coatings on HDG zinc substrate. Electrolyte in contact with the defect is  $0.86 \text{ mol dm}^{-3}$  NaCl: curve (a) = 120 min, (b) = 240 min, (c–e) at 120 min intervals.

concentration is required. Once interfacial  $\text{O}_2$  reduction begins, cations migrate towards the underfilm cathode, and anions migrate towards the defect anode, that is, anions from the experimental electrolyte are excluded from the electrolyte layer forming beneath the delaminated coating.<sup>30</sup>

In agreement with the earlier findings of Leidheiser<sup>1,27</sup> the value of  $k_d$  in eqn [1] was found to increase with the aqueous diffusion coefficient of the group I cation used in the experimental electrolyte, that is, in the order  $\text{Li}^+ < \text{Na}^+ < \text{K}^+ < \text{Cs}^+$ . The identity of the counter anion ( $\text{Br}^-$ ,  $\text{F}^-$ ,  $\text{Cl}^-$ ,  $\text{ClO}_4^-$ ) was found to have no influence on  $k_d$ , and the absence of anions in the under-film region was confirmed by Auger analysis.<sup>30</sup> The electrolyte layer forming beneath the delaminated coating was found to be 2–3  $\mu\text{m}$  thick. However, the diffusion coefficients calculated for cations migrating in this layer were calculated to be more than 10 times smaller than in aqueous solution. It was therefore proposed that the electrolyte layer takes the form of a gel comprising highly oxidized polymer in water.<sup>30</sup>

On the basis of the above, it would seem clear that the rate determining step in cathodic delamination is typically the transport of cations from the external electrolyte along the interface between the organic coating and the metal substrate. However, this notion should be regarded with caution because the coated

metal systems used to study the intrinsic kinetics of cathodic delamination have largely been ‘model’ systems comprising unpigmented polymer films coated onto metals which are good electrocatalysts for cathodic  $\text{O}_2$  reduction, and with no prior application of any chemical ‘pretreatment’ or ‘conversion coating’ to influence adhesion and/or rates of interfacial electron transfer. The rate determining step in any complex process is always the slowest step. In practical coated systems pigments capable of inhibiting cathodic oxygen reduction may be added to the organic coating, an inhibitory pretreatment applied to the metal substrate, or the elemental composition of the metal surface modified to reduce activity for oxygen reduction. Under these circumstances, the rates of cathodic delamination may be greatly diminished without any obvious influence on the facility of interfacial cation transport – as will be discussed further under *preventing cathodic delamination* given below.

#### 2.14.2.1 Disbondment Mechanism

A question arises as to exactly how the presence of cathodic  $\text{O}_2$  reduction and an alkaline environment produces disbondment of an organic coating from the underlying substrate. We should say immediately that it is very unlikely that any single, unique and universal disbondment mechanism exists. More

probably, there are a number of possible mechanisms that may occur alone or in combination depending on the nature of the coated metal system under consideration. In any particular system, the relevant mechanism will be that which proceeds at the fastest rate. Modifying the system to inhibit a particular mechanism may reduce the rate of cathodic delamination, but not prevent it completely if another mechanism is available.

The first possible mechanism is the alkaline dissolution of a preexisting (air-formed) oxide layer at the substrate–coating interface. In the case of metals such as zinc with strongly amphoteric oxides, which dissolve at moderately high pH, this would seem a reasonable hypothesis. Stratmann *et al.* have shown that the oxide layer on zinc actually thickens in the delaminated zone, but that this occurs via a dissolution–reprecipitation mechanism.<sup>32</sup> However, iron III oxides are only weakly amphoteric and dissolve only at very high pH (approaching 14). Consequently, the iron surface tends to remain passive in the delaminated zone.<sup>29</sup> Reduction of iron III to a more soluble iron II oxide is possible as potentials decrease.<sup>35</sup> However, Castle and Watts used X-ray photoelectron spectroscopy (XPS) to show that iron oxide within the delaminated region only became reduced in localized patches and that the delaminated region extended well beyond these.<sup>36</sup> They concluded that oxide dissolution is not a significant factor in cathodic delamination on iron.

The second possibility is that alkaline electrolyte physically displaces the coating at the substrate–coating interface.<sup>14</sup> Aqueous displacement was first suggested by Evans in terms of the ability of alkaline solution to creep over the metal surface.<sup>37</sup> The ‘wetability’ of an electrode surface increases with decreasing (electrolyte–electrode) interfacial energy and latter reaches a maximum at the potential of zero charge.<sup>38,39</sup> On this basis it has been pointed out that the affinity for water of an oxide covered metal surface will tend to increase as the pH becomes increasingly removed from the isoelectric point (pH point of zero charge) of that oxide.<sup>40</sup> If it is assumed that the isoelectric point lies near or below neutral pH, a competitive displacement of the coating by water will be promoted as pH, and therefore water affinity is increased. It has also been argued that competitive displacement may occur when oxide–polymer acid–base interactions make a significant contribution to coating adhesion.<sup>41</sup>

The third possibility is that alkaline electrolyte reacts directly with the coating polymer in such a way as to break covalent chemical bonds existing

within the coating or between the substrate and the coating. Carboxylic esters are known to undergo alkaline hydrolysis (saponification), and this process has long been thought of as important in cathodic delamination.<sup>36</sup> Many polyesters, epoxy esters, alkyd resins and other polymers bearing ester functionality are susceptible to hydrolysis; and so are polymers bearing urethane and urea linkages. It has been shown using XPS that coatings based on melamine–formaldehyde and urea–formaldehyde coatings cross linked with epoxy resin oligomers cathodically delaminating from steel in 5% aqueous NaCl showed chemical change consistent with hydrolysis of ester, urethane, and/or urea linkages.<sup>42,43</sup> The same studies also showed that the delaminated steel surface was covered with an organic residue indicative of cohesive failure within the coating. Conversely, for cross linked polybutadiene coatings, which develop only very limited quantities of carboxylic and ester functionality during oxidative curing, evidence of hydrolysis damage is limited to a layer of more highly oxidized polymer immediately adjacent to the substrate surface.<sup>44</sup> Castle and Watts concluded that, whilst there is no universally applicable mechanism of cathodic disbondment, the more resistant the coating polymer is to alkaline hydrolysis the more likely is an interfacial separation rather than a cohesive failure due to coating degradation.<sup>45</sup>

Stratmann *et al.* have pointed out that  $\text{OH}^-$  is not the only cathodically produced species capable of destroying iron–oxygen–polymer bonds such as  $\text{Fe-O-CO-R}$  (where  $\text{R} = \text{organic}$ ).<sup>31</sup> Many short lived intermediates of  $\text{O}_2$  reduction, such as  $\text{O}_2^{\cdot-}$ ,  $\text{HO}_2^{\cdot}$ ,  $\text{HO}_2^-$ ,  $\text{H}_2\text{O}_2$ , and  $\text{HO}^{\cdot}$  may be more reactive than  $\text{OH}^-$  itself. The same authors go on to show that an epoxy coated iron exposed to 1 M aqueous NaOH through a coating defect delaminates six times more slowly than the same system exposed to 1 M aqueous NaCl and held in the presence of air.<sup>31</sup> The intermediates of cathodic  $\text{O}_2$  reduction are capable of reacting with a wide range of organic functionalities (particularly in the case of  $\text{HO}^{\cdot}$ ). Consequently, in their presence, carboxylic ester functionality and/or other functionalities susceptible to alkaline hydrolysis are not required for polymer degradation or disbondment to occur.

### 2.14.2.2 Preventing Cathodic Delamination

Under circumstances where disbondment occurs through physical displacement of the coating it might reasonably be assumed that disbondment could be discouraged by promoting coating adhesion. Funke has

described adhesion as the most important and decisive property of a coating.<sup>46–48</sup> Functionalized silanes have been widely used as reactive coupling agents for improving the adhesion of organic coatings to steel. Examples include vinyl silanes for improving wet adhesion of alkyd coatings,<sup>49</sup> amino and epoxy silanes for epoxy/polyamide and polyurethane coatings,<sup>48</sup> and various other silanes for improving adhesion of automotive electrocoats.<sup>50</sup> Marsh *et al.* treated steel substrates with prehydrolyzed allyltriethoxysilane prior to coating with unpigmented alkyd resin.<sup>51</sup> They found that silanization improved both wet and dry adhesion but subsequently found no relationship between adhesion and rates of cathodic delamination. Leidheiser did find that treating an iron surface with silane prior to coating with polybutadiene resulted in significantly reduced rates of cathodic delamination.<sup>1</sup> However, it is not clear that this effect had anything to do with adhesion because impedance measurements on silane treated iron also showed large increases in charge transfer resistance and, therefore, decreased electrochemical activity for cathodic oxygen reduction.<sup>1</sup> Overall, it would seem that improving coating adhesion alone may not improve resistance to cathodic delamination if an alternative disbondment mechanism, such as hydrolysis of the coating polymer, is available.<sup>52</sup>

Inorganic pretreatments or conversion coatings are frequently applied to metal substrates prior to coating with paint or lacquer as a means of both promoting adhesion and chemically inhibiting corrosion.<sup>53</sup> Pretreatments based on phosphoric or chromic acids react electrochemically with the metal and substantially replace the air-formed oxide film with a layer of metal phosphate or mixed chromium oxide.<sup>53</sup> Such a layer may disfavor cathodic delamination if it is more resistant to alkaline dissolution than the original oxide layer, and/or if it inhibits cathodic O<sub>2</sub> reduction. It has long been proposed that resistance to alkaline dissolution determines resistance to cathodic delamination in the case of metal phosphate pretreatment layers.<sup>54,55</sup> A recent study has similarly concluded that interfacial stability is strongly influenced by the chemical stability of conversion layers to hydroxide generated by cathodic O<sub>2</sub> reduction.<sup>56</sup> However, SKP studies of thin phosphate-based conversion coatings on zinc (galvanized steel) have shown that these also inhibit cathodic O<sub>2</sub> reduction and produce a corresponding cathodic (negative) shift in the potential of the polymer coated surface.<sup>57</sup> This effect is attributed to the replacement of n-semiconducting zinc oxide with an electrically insulating zinc phosphate layer that obviously reduces the driving force for cathodic

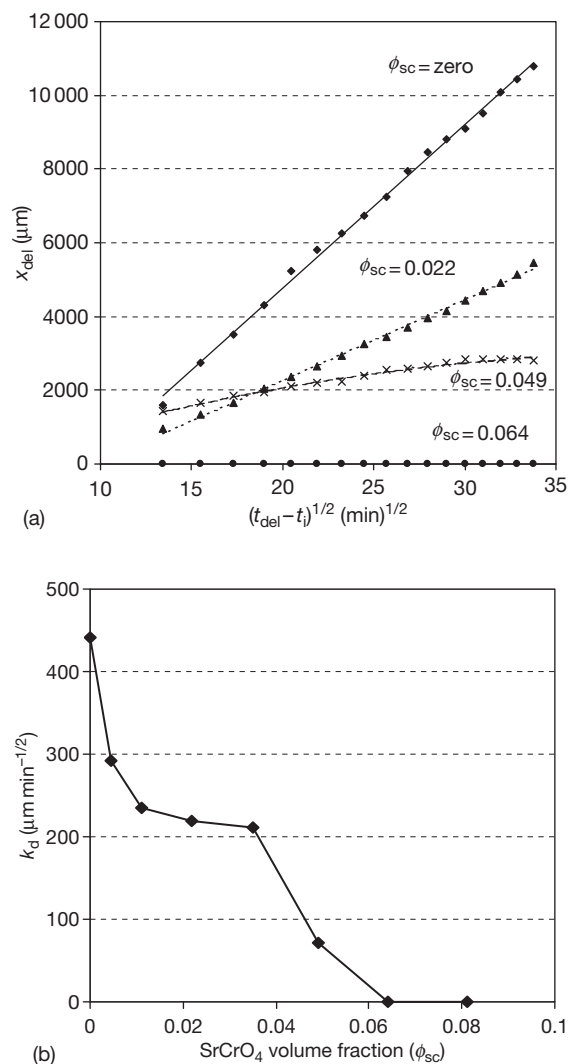

delamination. Similarly, SKP studies of chromate conversion coatings on galvanized steel have shown a cathodic potential shift relative to the unmodified zinc surface.<sup>58</sup> This finding might seem paradoxical at first given the oxidizing nature of chromium VI species. However, cathodic inhibition by chromate has been reported by a number of authors.<sup>59–61</sup>

Corrosion inhibitor pigments based on sparingly soluble salts or ion-exchange solids are often dispersed in paint coatings with the aim of preventing or retarding corrosion-driven coating failure. The SKP technique has been used to study the influence of strontium chromate (SrCrO<sub>4</sub>) pigment on the kinetics of cathodic delamination affecting polyvinylbutyral coatings adherent to the intact zinc surface of hot dip galvanized steel.<sup>62</sup> When the defective electrolyte was saturated with SrCrO<sub>4</sub>, CrO<sub>4</sub><sup>2−</sup> anions were excluded from the under-film electrolyte layer by the delamination cell electric field, and delamination rates were reduced by less than 25%. In contrast, dispersions of SrCrO<sub>4</sub> pigment in the PVB coating allowed CrO<sub>4</sub><sup>2−</sup> diffusion directly into the under-film electrolyte layer. Figure 4(a) shows a series of  $x_{\text{del}}$  versus  $(t_{\text{del}} - t_i)^{1/2}$  plots for various values of pigment volume fraction ( $\phi_{\text{SC}}$ ). The slopes of these plots decrease as  $\phi_{\text{SC}}$  increases and deviations from linearity consistent with departure from pure cation migration control occur for  $\phi_{\text{SC}} \geq 0.049$ . The dependence of  $k_d$  values, obtained from initial  $x_{\text{del}}$  versus  $(t_{\text{del}} - t_i)^{1/2}$  slopes, on  $\phi_{\text{SC}}$  is given in Figure 4(b), which shows that  $k_d$  tends to zero for  $\phi_{\text{SC}} = 0.064$ . On the basis of these findings, it was proposed that replacement of under-film O<sub>2</sub> reduction by a self-limiting reduction of CrO<sub>4</sub><sup>2−</sup> to insoluble Cr(III) (hydr)oxide is the most significant factor in decreasing delamination rates.<sup>62</sup>

When the same SKP approach was used to study dispersions of silica and bentonite based rare earth (Ce<sup>3+</sup>), cation-exchange pigments in a PVB coating on zinc (galvanized steel) Ce<sub>(aq)</sub><sup>3+</sup> was found to exchange directly into the under-film electrolyte and significantly retard coating delamination.<sup>63</sup> On a nonpretreated zinc surface, delamination was not halted completely because the under-film exchange of Na<sup>+</sup> by Ce<sup>3+</sup> was itself incomplete. The resulting precipitation of Ce(OH)<sub>3</sub> increased the under-film electrolyte layer resistivity, but, unlike the Cr(III) (hydr)oxide described above, Ce(OH)<sub>3</sub> did not form a coherent surface film capable of stifling O<sub>2</sub> reduction at the cathodic delamination front.<sup>27</sup> However, when the same cation-exchange pigments were used in conjunction with a chromate based pretreatment this appeared to influence the surface nucleation of Ce(OH)<sub>3</sub> to

produce a coherent film, stifling  $O_2$  reduction and producing a profound inhibition of cathodic delamination.<sup>64</sup> Lyon *et al.* have reported a similar synergistic activity between zinc–phosphate and commercial  $Ca^{2+}$  cation-exchanged silica (Shieldex™).<sup>65</sup>

There has been recent interest in the use of intrinsically conducting polymers (ICPs) for corrosion control and the topic has been subject to review.<sup>66,67</sup> Many studies have focused on polyaniline (PAni).<sup>68–70</sup> PAni exists in various states interrelated by the redox and acid–base equilibria<sup>71,72</sup> but it is the emeraldine

**Figure 4** Delamination kinetics for  $SrCrO_4$  pigmented  $30 \mu m$  PVB coatings on HDG zinc substrate. Electrolyte in contact with the defect is uninhibited  $0.86 \text{ mol dm}^{-3}$  NaCl. (a) Plots of  $x_{del}$  versus  $(t_{del} - t_i)^{1/2}$  for varying  $SrCrO_4$  volume fraction ( $\phi_{sc}$ ). salt (ES) which is electronically conductive and most widely used for corrosion control. The ES is produced by protonating or ‘doping’ the partially oxidized PAni emeraldine base (EB) using Bronsted acids.<sup>73–76</sup> PAni ES may be applied to metal surfaces directly by electrodeposition<sup>77,78</sup> or deposition of water-borne dispersions.<sup>79</sup> However, PAni ES particles may also be dispersed in a conventional polymer binder.<sup>80,81</sup> The protection of carbon steel by PAni ES has been variously ascribed to substrate ennoblement, the formation of a passive oxide film and anodic inhibition through precipitation of an insoluble metal salt of the dopant anion.<sup>66,67</sup> The ES/LB (leuco base) redox couple is generally regarded as being responsible for establishing substrate potentials in the passive regime.<sup>67,69,72,82</sup> Furthermore, it has been suggested that PAni ES becoming reduced to LB is cyclically reoxidized by the atmospheric  $O_2$ , thus extending the period of ennoblement.<sup>67,69,71,72,83,84</sup> It has also been proposed that the displacement of cathodic oxygen reduction away from the metal–coating interface acts to suppress cathodic delamination.<sup>66,82,85</sup>

This last notion has been investigated using coatings comprising various volume fractions of particulate polyaniline (PAni) dispersed in a polyvinylbutyral binder applied to iron substrates.<sup>86,87</sup> SKP was used to measure substrate potentials in air and follow corrosion-driven cathodic delamination when 5% (w/v) (0.86 M) aqueous NaCl was brought into contact with a coating defect. PAni EB was found to have no effect on either substrate potential or delamination kinetics. **Figure 5** shows delamination kinetics for various

**Figure 5** Plots of  $x_{del}$  versus time for  $30 \mu m$  PVB/PAni-pTS coatings on iron with various PAni-pTS pigment volume fractions ( $\phi_{pa}$ ). In each case, the electrolyte in contact with the defect is  $0.86 \text{ mol dm}^{-3}$  NaCl (aq).  $\phi_{pa}$  key: (i) 0, (ii) 0.05 (iii) 0.1 (iv) 0.15 (v) 0.2, and (vi) 0.25.

volume fractions ( $\phi_{pa}$ ) of *p*-toluene sulfonic acid doped Pani ES (Pani-pTS). It may be seen that when  $\phi_{pa} \geq 0.05$  the  $x_{del}$  increases linearly with  $t_{del}$  and not parabolically according to eqn [1]. Delamination rate ( $dx_{del}/dt_{del}$ ) decreases monotonically from 12.8 to  $0.83 \mu\text{m min}^{-1}$  as  $\phi_{pa}$  is increased from 0.05 to 0.25, a finding summarized in curve (ii) of Figure 6. Curve (i) of Figure 6 shows the mean  $E_{intact}$  (potential of undelaminated surface) values plotted versus  $\phi_{pa}$ . The critical volume fraction required for long-range electrical conduction in a percolating network is  $\sim 0.17^{88}$  and  $E_{intact}$  appears to become constant and determined by the PANi ES/EB couple for  $\phi_{pa} \geq 0.2$ .

PAni ES doped using *p*-toluenesulfonic (H-pTS), camphorsulfonic (H-CS), phosphoric ( $\text{H}_3\text{PO}_4$ ) and phenylphosphonic ( $\text{H}_2\text{-PP}$ ) acids increased substrate potentials by up to 0.36 V and inhibited cathodic delamination, with the efficiency order  $\text{H-pTS} < \text{H-CS} < \text{H}_3\text{PO}_4 = \text{H}_2\text{-PP}$ .<sup>87</sup> Conversely, dopant sodium salts added to the corrosive electrolyte when the coating did not contain PANi were not found to inhibit delamination. On this basis, it is concluded that, on iron, the inhibition of cathodic delamination by polyaniline did arise primarily from cathodic  $\text{O}_2$  reduction becoming relocated from the ennobled substrate onto the coating ES. However,  $\text{Fe}_3(\text{PO}_4)_2$  and FePP salt films formed through redox reactions at the ES–substrate interface also contributed by hindering electron transfer at the substrate surface. Without these ‘chemical’ contributions to inhibition, ES could

only slow up cathodic delamination on iron and not prevent it.<sup>86,87</sup> It should also be noted that the reoxidation of LB to ES is only likely to occur at significant rates when the coating is in contact with air, that is under nonimmersion conditions. PANi is therefore unlikely to be of significant benefit when a coated metal is immersed in aqueous electrolyte.

### 2.14.2.3 Modifying Metal Composition

Metals differ considerably in their electrocatalytic activity for cathodic oxygen reduction. Pure aluminum, for example, is virtually inactive as an oxygen cathode.<sup>89</sup> This inert behavior probably reflects the electronic properties of the surface aluminum oxide that, as an electrical insulator with a wide band gap, disfavors interfacial electron transfer. Ion implantation of aluminum or titanium into iron has been shown to reduce both surface activity and rates of cathodic delamination.<sup>1,90</sup> Hydrated oxide or hydroxide layers produced through the interaction of group II (alkaline earth) metal cations with hydroxide anions are similarly known to act as effective blockers of cathodic  $\text{O}_2$  reduction.<sup>91</sup> On this basis, alloying with aluminum and/or group II elements might reasonably be expected to reduce the susceptibility of a given metal to cathodic delamination. In structural metals, the scope for alloy development is limited by the need to preserve the mechanical properties. In metallic coatings, there is greater freedom, and significant advances have been seen in the field of zinc-based (galvanized) coatings for steel.<sup>92</sup>

Souto and Scantlebury have shown that hot dip galvanized steels in which the zinc layer is alloyed with 5% aluminum (Galfan) and 55% aluminum (Aluzinc) exhibit a much increased resistance to cathodic delamination relative to a conventional (zinc only) system.<sup>93</sup> Paradoxically, when the same Zn and Zn–Al alloy coatings were studied using a rotating disc electrode all three were found to be highly active  $\text{O}_2$  cathodes.<sup>21</sup> This suggests that the improved delamination resistance exhibited by the Zn–Al alloy coatings results from a fragmentation of cathodic sites rather than general surface deactivation. That is to say the heterogeneous microstructure of the Zn–Al alloy coatings, consisting as it does of interlocking zinc-rich and aluminum-rich phases, is reflected in local composition of the interfacial oxide layer. Blocking of electron transfer over aluminum-rich oxide regions would then disfavor the formation of a continuous delamination front and prevent the front from advancing from one zinc-rich region to the next.

**Figure 6** Summary plot (a)  $E_{intact}$  and (b) delamination rate ( $dx_{del}/dt$ ) as a function of  $\phi_{pa}$  for  $30 \mu\text{m}$  PVB/PAni-pTS. Initial  $dx_{del}/dt_{del}$  is plotted in the case of the PVB ( $\phi_{pa} = 0$ ) coating.

Stratmann *et al.* used SKP to show that cathodic delamination occurred rapidly on zinc (electrogalvanized steel) but not on the zinc-rich intermetallic phase  $\text{MgZn}_2$ , which frequently forms in Zn–Mg alloy coatings.<sup>94</sup> The potential of the intact  $\text{MgZn}_2$ –oxide–polymer interface was found to be  $\sim 0.7$  V more negative than the corresponding Zn–oxide–polymer interface. This increase in cathodic polarization was attributed to a large band gap in the  $\text{MgZn}_2$  interfacial oxide, resembling that of  $\text{MgO}$ . Dissolution of magnesium oxide under cathodic conditions is unlikely because group II oxides are basic and become more insoluble as pH increases. However,  $\text{MgZn}_2$  exposed to neutral aqueous NaCl at an organic coating defect was found to become rapidly dealloyed through Mg dissolution. In so doing, the defect potential rose to resemble freely corroding zinc ( $-0.7$  V vs SHE). Potentials in the defect were actually higher than those in the intact coated area and no driving force existed for cathodic delamination.<sup>94</sup>

### 2.14.3 Filiform Corrosion

An underfilm corrosion phenomenon, producing ‘hair-like’ corrosion tracks on lacquer-coated steel, was first reported in the scientific literature by Sharman in 1944,<sup>95</sup> who used the phrase FFC to describe these features. FFC is regarded as a type of atmospheric corrosion, principally affecting organic-coated iron (steel) and aluminum surfaces, initiating at penetrative coating defects and producing characteristic thread-like under-film deposits of corrosion product. An example of the typical appearance of corrosion filaments on organic coated aerospace aluminum alloy is given in [Figure 7](#). Although FFC attack is largely considered to be superficial in nature, it is aesthetically unpleasant and hence undesirable in modern organic-coated metal products.

Much of the research carried out in FFC prior to 1995 has been comprehensively reviewed elsewhere.<sup>5,6</sup>

**Figure 7** Filiform corrosion observed on aluminum alloy AA2024-T3 coated with a clear film of PVB.

It is not our intention to recover the same ground, but rather to give a general overview of FFC and a subsequent outline of recent developments in the field.

#### 2.14.3.1 General FFC Characteristics

It is generally accepted that FFC initiates when aggressive species, such as chloride ions, permeate through an organic coating, usually at a defect or weakness in the coating and accumulate at the metal–coating interface. FFC only occurs in the presence of atmospheric oxygen and high humidity, although the humidity range over which corrosion is observed is dependent upon the metal studied. Slabaugh *et al.*<sup>96</sup> observed FFC occurrence over a 30–95% relative humidity range for common aerospace aluminum alloys coated with a range of organic coating types, while FFC activity on iron (steel) samples is reported to cease at humidity levels below 60%.<sup>5</sup> The motion of individual corrosion filaments is largely directionally stable, propagating in relatively straight lines for appreciable distances. It has also been reported that filaments growing on aluminum alloy surfaces do so preferentially along the rolling or extrusion axis.<sup>6,97</sup> Such behavior is thought to arise from corrosion filaments following a ‘path of least resistance’ formed by lines of intermetallic precipitates present at the elongated grain boundaries of the rolled/extruded alloy microstructure. Corrosion filaments do not generally cross each other, nor do they propagate through a break in the surface coating.<sup>5</sup>

Corrosion filaments consist of a mobile, electrolyte-filled head, containing metal cations and aggressive anions (such as  $\text{Cl}^-$ ), and a tail of dry, porous corrosion product. FFC head regions typically exhibit a low pH towards their leading edge (as low as pH 1) as a consequence of cation hydrolysis. The primary driving force for filament advancement is thought to be differential aeration, arising from facile mass transport of gaseous  $\text{O}_2$  through the filament-tail. The oxygen concentration cell formed directs anodic metal dissolution towards the leading-edge of the filament-head, while the principal site of cathodic oxygen reduction lies towards the trailing-edge of the active head. Aggressive anions ( $\text{Cl}^-$ ) and water are conserved in the filament head electrolyte and corrosion filaments are reported to continue propagating for long periods of time (months or years). Although these general principles are considered to hold true for FFC on both aluminum and iron surfaces, there are notable mechanistic differences,

and these will be discussed separately for each type of surface in the following sections.

It should also be noted that there are several anecdotal reports of FFC observed on coated magnesium surfaces.<sup>5,6,98,99</sup> However, magnesium underfilm corrosion has received relatively little in the way of scientific study and a description of FFC remains limited to observations of vigorous  $H_2$  evolution and a low pH (2–3) within electrolyte filled head regions.<sup>99</sup> In fact, there seems to be a degree of confusion regarding magnesium FFC, as the term is commonly used to describe a type of localized corrosion observed when magnesium and its alloys are immersed in bulk chloride-containing electrolyte.<sup>100,101</sup>

### 2.14.3.2 FFC on Aluminum Surfaces

Filiform activity on aluminum has been shown to initiate at a range of different coating discontinuity sites such as cut edges,<sup>5,96</sup> scratches<sup>6,96–98,102</sup> and rivet heads.<sup>6,99</sup> At such defects, the presence of contaminating salts, such as chlorides will have resulted in production of  $AlCl_3$  and  $Al(III)$  oxychloride salts ( $Al(OH)_2Cl$  and  $Al(OH)Cl_2$ ) at the exposed aluminum surface. The dissolution of these salts in the adsorbed humidity film present at high humidity subsequently produces an aqueous electrolyte capable of supporting corrosion. Chloride is known to disrupt the passivity of aluminum by reacting with the protective aluminum (hydr)oxide film to produce water soluble aluminum (III) oxychloride complexes. The passive layer breakdown is usually local in nature, resulting in the initiation of highly localized sites of anodic metal dissolution and producing pit-like excavations of the aluminum surface. The generation of the active heads of propagating FFC filaments probably results from the migration of such sites beneath coated regions adjacent to a penetrative defect. **Figure 8(a)** shows a possible mechanism by which corrosion filaments may become initiated through the presence of differential aeration. In this scheme, it is assumed that oxygen transport to the metal surface through the thin adsorbed electrolyte film at the exposed aluminum surface is significantly easier than through a relatively thick organic coating. Hence cathodic oxygen reduction is favored on the bare metal while anodic aluminum dissolution will tend to become concentrated at the  $O_2$ -deficient metal–electrolyte–coating interface. Correspondingly, the coating will become undercut while  $Cl^-$  ions will migrate beneath the delaminated coating to preserve

**Figure 8** Schematic diagram showing the processes involved during (a) initiation and (b) propagation of a corrosion filament. A SKP-derived free corrosion potential distribution, measured along the length of a propagating filament on organic-coated AA2024-T3, showing typical  $E_{corr}$  values in each separate region is also given in (b).

electroneutrality and water will be drawn in by osmosis to produce an electrolyte droplet.

Once initiated, corrosion filaments propagate away from the coating defect, under the influence of an  $O_2$  concentration cell of the type represented schematically in **Figure 8(b)**. Aluminum (III) cations produced by anodic dissolution at the leading edge of the filament head migrate towards a cathodic region at the trailing edge of the active head and combine with  $OH^-$  anions generated by cathodic oxygen reduction. Stepwise hydrolysis of  $Al^{3+}$  (or more

correctly  $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$  cations eventually leads to the precipitation of the water insoluble corrosion product  $\text{Al}(\text{OH})_3$ . **Figure 8(b)** also includes an empirically-derived free corrosion potential ( $E_{\text{corr}}$ ) profile, obtained along the length of a propagating filament on aluminum by SKP potentiometry.<sup>103</sup> The profile shows that  $E_{\text{corr}}$  values tend to be lower towards the leading edge of the FFC active head and higher towards the trailing edge. This is consistent with the extent of anodic depolarization, and hence anodic dissolution, being greatest at the leading edge.

Constant migration of  $\text{Cl}^-$  anions toward the anodic leading edge results in the retention of all water-soluble ions and, through osmosis, all liquid water within the FFC active head. Several authors have used surface analysis techniques such as secondary ion mass spectrometry (SIMS)<sup>103</sup> and X-ray emission<sup>104</sup> to demonstrate that  $\text{Cl}^-$  ions applied at a penetrative defect are conserved within the filament head, with little evidence of entrapment in defect or tail regions of the FFC-affected surface. The high  $E_{\text{corr}}$  values observed in the tail region of the FFC filament represented in **Figure 2(b)** is due to the deposition of a thick, substantially dry, hydrated aluminum (III) oxide ( $\text{Al}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ ) layer, formed as an  $\text{Al}(\text{OH})_3$  corrosion product left behind in the wake of the advancing filament head slowly losing water. Relatively easy  $\text{O}_2$  diffusion through the porous  $\text{Al}_2\text{O}_3 \cdot x\text{H}_2\text{O}$  deposit allows the FFC differential aeration cell, and hence filament propagation, to be maintained over significant distances. The high  $E_{\text{corr}}$  values observed in the FFC tail imply increased passivity in these regions, which may help to explain empirical observations that individual corrosion filaments generally avoid intersecting others.<sup>6</sup> Such highly passive areas would tend to disfavor further anodic activity, and an encroaching FFC head region would be forced to redirect onto adjacent uncorroded areas.

Several authors have observed the formation of hydrogen gas bubbles within filament heads produced on aluminum surfaces.<sup>6,96,105</sup> Hoch employed pH indicator dyes incorporated within organic coatings to determine pH values of 2–3 at leading edges of aluminum filament head.<sup>99</sup> Such levels of acidity will tend to maintain active aluminum dissolution in these regions. A combination of low pH, caused by proton release via partial hydrolysis of  $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$  cations, negative  $E_{\text{corr}}$  values of  $\sim -0.5$  V versus SHE,<sup>103</sup> along with oxygen deficiency at the leading edge of the filament head are thought to result in a secondary cathodic reaction involving hydrogen evolution.

Experimental support for an anodic disbondment mechanism of FFC on aluminum is principally derived from the observations of FFC behavior under different  $\text{O}_2$  transport regimes. Ruggieri and Beck<sup>5</sup> showed that FFC advancement ceased when filament tails were sealed in such a way as to halt the ingress of air. They also demonstrated that stationary filaments became reactivated when organic coatings above tail regions were cut open. Lenderink<sup>102</sup> provided further support for the importance of through-tail  $\text{O}_2$  diffusion by reporting that FFC propagation rates remained unaffected on samples where a metal foil had been deposited over the organic coating to obstruct through-coating  $\text{O}_2$  transport.

The use of conventional electrochemical techniques to study FFC has routinely been limited by the absence of bulk electrolyte, the presence of highly resistive organic coatings and the small size of the local corrosion cell. However, in the last decade, significant developments in the SKP have greatly facilitated the quantitative electrochemical investigation of FFC. It has been shown that SKP is capable of visualizing the free corrosion potential ( $E_{\text{corr}}$ ) distributions associated with individual corrosion filaments.<sup>106–108</sup> *In situ*, SKP scanning has also been used to generate a series of time-dependent  $E_{\text{corr}}$  distribution patterns that provide information on filament initiation, propagation, and termination rates within a filament population.<sup>97,103</sup> FFC propagation rates on AA2024-T3, quantified by SKP,<sup>103</sup> are shown to be strongly dependent on the quantity of the initiating chloride, confirming that the ability to control the quantity of chloride ion entering a filament-head population is critical to the reproducibility of any quantitative FFC test procedure. Other *in situ* techniques, such as Fourier transform infrared (FTIR) microspectroscopy, have also been used in conjunction with SKP scanning to give additional information regarding the constituent salts present within propagating electrolyte-filled FFC heads.<sup>109</sup>

The same *in situ* techniques have also been employed to study inhibition of FFC by in-coating pigments based on both conventional Cr(VI) chemistry<sup>110</sup> and novel anion-exchange hydrotalcite minerals.<sup>111–113</sup> Previous *ex situ* studies, using a combination of electron microscopy and X-ray and SIMS techniques, showed that Cr(VI) species inhibit FFC on copper-containing AA2024 primarily by stifling S-phase particle dealloying and subsequent cathodic  $\text{O}_2$  reduction. *In situ* SKP studies confirmed this finding, but in addition demonstrated that a significant depression in  $E_{\text{corr}}$  of the intact coated metal

surface resulted from a reversible, nonfaradaic adsorption of Cr(VI) species, which also contributed to FFC inhibition.<sup>110</sup>

### 2.14.3.3 Surface-Active FFC on Aluminum

Within the last decade it has been established that thermo-mechanical processing and/or shear deformation of aluminum alloys can produce a surface microstructure which differs considerably from the bulk.<sup>114–123</sup> Deformed aluminum alloy surface layers are typically up to a few micrometers thick, consisting of fine, submicron grain sizes where the presence of second phase particles stabilize grain boundaries and prevent recrystallization. Many researchers have so far demonstrated that a strong correlation exists between the presence of a deformed surface layer and susceptibility of painted alloy samples to FFC.<sup>114–123</sup> In several cases, the severity of FFC attack is increased by heat treatment, and attributed to thermally-promoted precipitation of intermetallic particles in the surface layer. The morphology of FFC on surface-activated samples is considered to differ from that discussed in the previous section and shown in Figure 7. FFC attack on samples comprising a deformed surface layer proceeds rapidly and is highly cosmetic and superficial in nature, limited only to the depth of the surface layer itself. Frequently FFC takes the form of numerous narrow filaments, propagating on a parallel course and separated laterally by only small distances, giving the impression of a single coalesced corrosion front. Figure 9 shows this type of cosmetic FFC affecting automotive alloy AA6016-T4 coated with a clear

organic film, where corrosion was initiated by controlled application of aqueous hydrochloric acid to a penetrative coating defect.

Surface-active FFC has been reported on a wide range of alloys, ranging from model Al-Fe-Mg-Si<sup>123</sup> and binary Al-X (X = Fe, Cu, Mn and Mg)<sup>120</sup> systems through to automotive and architectural 5000<sup>118,122</sup> and 8000<sup>114–116</sup> series alloys. However, the majority of research in this area has concentrated on 3000 (Al-Mn)<sup>114–119,121</sup> and 6000 (Al-Mg-Si)<sup>124–128</sup> series alloys designed for automotive panel applications. The increased FFC susceptibility of AA3005 samples comprising damaged surface layers is thought to derive from preferential precipitation of noble Mn and Fe rich intermetallics,<sup>119</sup> leading to a cathodic activation of the surface layer with respect to the bulk alloy. Several authors have confirmed that when the surface layer is removed, the extent of FFC is considerably reduced and the type of attack is restricted to a much slower ‘deep pitting’ mode of corrosion,<sup>117,122</sup> more closely resembling the type of features shown in Figure 6.

*In situ* SKP potentiometry has recently been used to follow the kinetics of FFC propagation and measure underfilm corrosion potentials associated with head and tail regions of surface-active FFC affecting organic-coated AA6016.<sup>125</sup> The authors report that for this alloy, surface abrasion and subsequent heat-treatment produces a significant depression in surface potential compared with the bulk material and this forms an additional thermodynamic driving force for rapid ‘surface-active’ corrosion. They conclude that although differential aeration remains a major driving force for FFC propagation, the filament cell potential will also contain a contribution arising from the dissimilar electrochemical characteristics of the surface deformed layer present at the leading edge of the FFC head and bulk alloy exposed by layer dissolution. A schematic representation of the mechanism of ‘surface-active’ FFC, where the deformed layer reacts as a sacrificial anode with respect to bulk AA6016, is given in Figure 10. Also included is a representation of the expected relationship of corrosion potential with distance across the FFC cell, confirmed empirically by *in situ* SKP measurements.<sup>125</sup>

Several authors have shown that problems of increased FFC susceptibility, through the introduction of a damaged layer by thermomechanical alloy processing, can be controlled by etching the surface using acid or alkali cleaner prior to coating.<sup>117,122,125</sup> However, automotive manufacturers frequently rectify surface defects in formed panels by mechanical

**Figure 9** Filiform corrosion observed on aluminum alloy AA6016-T4 overcoated using PVB. Courtesy of A. Coleman.

**Figure 10** Schematic representation of the physical regions within a surface active FFC corrosion cell and proposed relationship with SKP-derived corrosion potential versus distance profiles.

grinding immediately prior to pretreatment and painting. This procedure reintroduces a deformed layer, subsequently reactivating the surface with respect to FFC and is liable to serious underfilm cosmetic failure. To avoid the introduction of a costly postgrinding etch or cleaning process, researchers are investigating new coating and/or pretreatment technologies which are capable of inhibiting FFC attack on surface-damaged alloys. To date, coatings based on phenylphosphonic acid dissolved in a polyvinylbutyral matrix are among the most promising candidates, demonstrating profound inhibition of FFC on AA6111-T4 automotive alloy samples comprising shear-deformed surface active layers.<sup>126</sup>

#### 2.14.3.4 FFC on Iron (Steel) Surfaces

The general consensus regarding the mechanism of FFC on iron is that filament advance remains driven by differential aeration,<sup>5,6</sup> arising from facile mass transport of atmospheric  $O_2$  through the filament-tail. As in the case of aluminum, cathodic oxygen reduction is considered to be localized at the droplet trailing-edge and anodic metal dissolution located at

the leading-edge of the electrolyte filled head. However, although this anodic disbondment mechanism is largely accepted for FFC on aluminum, there persists some controversy regarding the location of the anodic and cathodic sites for corrosion filaments propagating on a coated iron surface. Since, as discussed in the preceding section, organic-coated iron surfaces are well known to undergo corrosion-driven delamination via a cathodic disbondment route, several authors have suggested that a similar process plays a major role in the mechanism of FFC on iron. In this alternative mechanism, cathodic activity is proposed to occur in a narrow area in the front part of the filament head,<sup>6,102,129</sup> although it has also been suggested that a site of cathodic activity exists a small distance in front of the filament leading edge.<sup>130,131</sup> Drawing on observations previously noted for blister formation on steel, Funke<sup>130,131</sup> proposes a mechanism whereby FFC is characterized by the development of an underfilm cathode, which precedes the head electrolyte droplet. This cathodic region appears at some distance from the front of the head and grows due to the generation of underfilm hydroxyl ions, up to a point where the trailing filiform head draws near and the two regions merge. At this point  $OH^-$  ions migrate towards the anode while metal cations present within the head electrolyte migrate forward in the direction of the preceding cathode. This results in a polarity reversal where the previously cathodic front region is transformed to become the anodic leading edge of the filiform head. The whole process is then repeated and is considered to be consistent with both the observed saltatory (jumping) movement of FFC on iron and the segmented appearance of corrosion tracks. A schematic representation of this theory is shown in Figure 11.

Ruggieri and Beck<sup>5</sup> dispute this hypothesis, pointing out that the model is inconsistent with asymmetric separation of the cathodic and anodic zones in the corrosion cell, and that previous studies had shown no experimental evidence of cathodic detachment in the vicinity of the propagating filaments. In addition, since the preceding cathode directs the FFC, it is implicit that ionic current must flow from the anode through the coating. The size of the cathode would thus be limited by the high resistance of an adherent metal-coating interface. It could however be argued that diffusion of ions from the preceding cathodic area to the head might occur through a layer of adsorbed water existing at the coating-metal interface. Ruggieri and Beck calculate that the thickness of the aqueous layer required would be  $3.5 \times 10^{-5}$  mm,<sup>5</sup>

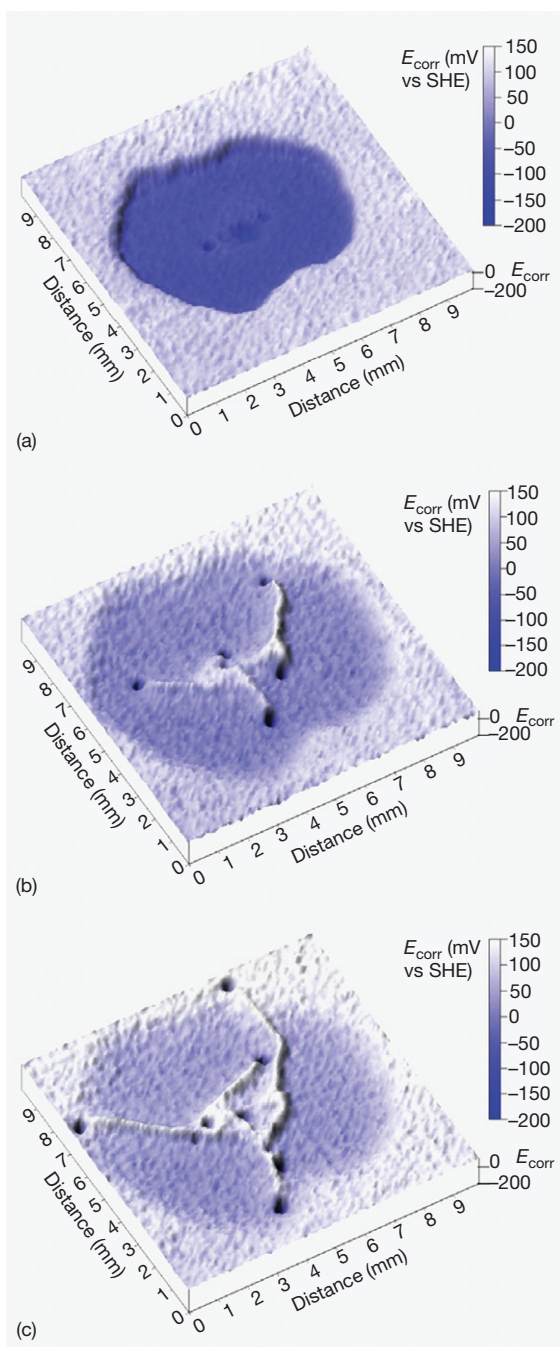

**Figure 11** Filiform corrosion via a cathodic disbondment mechanism as proposed by Funke<sup>130,131</sup> for a protective organic coating on iron (steel).

which would tend to indicate a region of coating disbondment. As mentioned previously, the lack of empirical observation of the regions of coating disbondment preceding a propagating filiform head is taken as a further argument for rejecting the cathodic disbondment FFC mechanism.

Another point of debate concerns the role of the cation associated with the initiating anion (usually chloride). Several authors argue that although initiating anions are conserved in the filament head electrolyte, the corresponding cations present consist solely of  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  produced by the metallic corrosion process.<sup>132,133</sup> X-ray spectroscopic and SIMS evidence are presented showing that filament heads do not contain the cation of the initiating salt. Therefore, if corrosion is initiated by applying a salt such as a group (I) chloride to a penetrative coating defect, then a question mark arises as to the eventual fate of the group (I) cations.

To address this issue Williams and McMurray<sup>133</sup> used a combination of *in situ* SKP and *ex situ* imaging SIMS measurements to elucidate the role of group (I) cations in the initiation of FFC on iron by aqueous group (I) chloride salts and to additionally determine the contribution of cathodic disbondment processes in filament propagation. It was demonstrated that group (I) chloride – initiated FFC proceeded via a two stage mechanism. Phase 1 of the underfilm corrosion process comprised the radial growth of a depassivated, roughly circular area surrounding the penetrative defect onto which a controlled quantity of initiating group (I) chloride was originally applied, indicating localized anodic iron dissolution at the defect site coupled to cathodic delamination of the surrounding coating. Imaging SIMS confirmed that the area was abundant in the group (I) cation associated with the initiating salt, showing that phase 1 consisted of group (I) cation migration beneath the delaminating coating to form an alkaline under-film electrolyte layer. As phase 1 continued, group (I) cations became progressively replaced in the vicinity of the defect site by  $\text{Fe}^{2+}$  cations, which in turn were prevented from entering the alkaline under-film layer due to the insolubility of  $\text{Fe(II)}$  hydroxide. Once group (I) cations were exhausted in the defect region, phase 1 cathodic delamination ceased and phase II commenced, where a polarity reversal occurred in which anodic activity was driven beneath the delaminated coating. Underfilm anodic fragments formed corrosion filament heads which propagated across the well-defined circular zone of cathodically delaminated coating left by phase 1 at a constant speed of  $\sim 0.3 \mu\text{m min}^{-1}$ . Filaments were also shown to propagate beyond this zone with only a minimal decrease in velocity. For these filaments no evidence of cathodic activity preceding the head region was observed. The entire process is exemplified by the selection of  $E_{\text{corr}}$  distribution maps, obtained by *in situ* SKP scanning of a PVB-coated iron sample after initiation of under-film corrosion using a controlled quantity of NaCl, given in Figure 12. When  $\text{FeCl}_2$  was substituted for NaCl as the initiating salt, a cathodic delamination phase was not observed, although FFC occurred as before and propagation rates similar to those initiated with group (I) chlorides were measured. Because filament velocities were similar beneath cathodically delaminated and intact coatings, it was concluded that cathodic delamination cannot be a rate determining step in the propagation of FFC on organic-coated iron.<sup>133</sup>

**Figure 12** Surface maps showing  $E_{\text{corr}}$  distributions measured over a PVB coated iron surface at  $t =$  (a) 16, (b) 130, and (c) 240 h, following initiation of underfilm corrosion at a penetrative coating defect using  $2 \mu\text{l}$  of  $10^{-3} \text{ mol dm}^{-3}$  NaCl (aq). (a) shows an initial cathodic disbondment process (phase 1), while (b) and (c) respectively demonstrate the propagation of corrosion filaments both within and beyond the boundary of the well defined, cathodically delaminated zone (phase II).

The findings of this work imply that the hydrolytic instability of ferrous ions, generated by underfilm anodic activity, precludes  $\text{Fe}^{2+}$  cations from coupling with remote cathode sites in both phases of the corrosion process. However, the possibility of short range coupling over distances of  $<0.1 \text{ mm}$ , that is, less than the lateral resolution of the SKP used in this study, cannot be ruled out. Indeed a subsequent higher resolution scanning Kelvin probe force microscope (SKPFM) investigation of iron FFC identified a possible cathodic area  $\sim 10\text{--}20 \mu\text{m}$  in front of the principally anodic leading edge of the head electrolyte. A recent time-lapse photographic investigation of individual corrosion filaments propagating on iron has shown that dark rings of a similar dimension form at the anterior of electrolyte filled heads,<sup>134</sup> and are associated with the saltatory motion of FFC. A photographic image showing this phenomenon, recorded using an optical microscope under reflective illumination, is given in Figure 13. It is considered that an increase in local pH at the head perimeter, caused by facile through-coating oxygen ingress at this point is responsible for the ring formation. When oxygen was excluded from the environment in contact with the filament head, but allowed to ingress through the porous tail, filaments continued to propagate at the same rate measured in air. However, under these conditions, neither ring formation nor filament saltation was observed and the filament advancement was steady in nature. The authors conclude that this apparent anterior cathodic activity is not a rate determining process in FFC on iron, but is an important factor in constraining the lateral spread of filament head electrolyte.<sup>134</sup>

**$y^+$**  Normalized (dimensionless) wall distance

**$Z$**  Number of charges

**$\delta_{Pr}$**  Prandtl's boundary layer thickness

**$\Delta c$**  Concentration gradient ( $\text{mol m}^{-3}$ )

**$\Delta p, \Delta P$**  Pressure loss (Pa)

**$\epsilon$**  Relative roughness

**$\lambda$**  Tube friction factor

**$\mu$**  Hydrodynamic viscosity (Pa s)

**$\nu$**  Kinematic viscosity of flowing fluid ( $\text{m}^2 \text{s}^{-1}$ )

**$\omega$**  Wave frequency/rotational speed ( $\text{s}^{-1}$ )

**$\Phi_{\text{destruct}}$**  Rate of scale destruction

**$\Phi_{\text{scale}}$**  Rate of scale formation

**$\rho$**  Density ( $\text{kg m}^{-3}$ )

**$\sigma_B$**  Fracture stress of the scales (Pa)

**$\tau_{RC}$**  Wall shear stress in rotated cage (Pa,  $\text{N m}^{-2}$ )

**$\tau_w$**  Wall shear stress (Pa,  $\text{N m}^{-2}$ )

## 2.13.1 Introduction

Flowing media are encountered in nearly all technical systems, for example, in heat exchangers, pumps, hydraulic machines, steam generators, different components of power stations, chemical plants, and the oil and gas industry, and in many cases, corrosion failures occurred due to flow effects. Understanding the mechanisms involved needs a detailed knowledge of both corrosion (specifically electrochemical corrosion) and fluid dynamics.

On the corrosion side, the type of material and the status of its surface (scale-free or scale-covered) are decisive. On the fluid dynamics side, the type of flow regime must be considered (developed laminar and turbulent flow; disturbed flow; one-phase, two-phase, multiphase flow without and with solid particles; and in the case of multiphase flow, horizontal, inclined, and vertical flow).<sup>1–11</sup>

## 2.13.2 Flow Dynamic Basics

### 2.13.2.1 Laminar and Turbulent Flow

The intensity of flow can be characterized as either laminar or turbulent. In laminar pipe flow, the profile of the local flow velocity,  $u_r$ , is parabolic (Figure 1(a)) and can be calculated according to eqn [1].<sup>12</sup>

$$u_r = u_c [1 - (y/R)^2] \quad [1]$$

where  $u_r$  is the axial velocity,  $u_c$  is the velocity at the pipe centerline,  $y$  is the axial position, and  $R$  is the inner radius of the pipe. Equation [1] is an analytical solution of the Navier–Stokes equation and the continuity equations of the fluid flow.

**Figure 1** Velocity profile in (a) laminar flow and (b) turbulent flow.

In turbulent pipe flow, the profile of the local flow velocity,  $u_r$ , is logarithmic (**Figure 1(b)**) and can be calculated according to **eqn [2]**.<sup>12</sup>

$$u_r = u_c [1 - (y/R)]^{1/n} \quad [2]$$

where  $n$  depends on the Reynolds number ( $Re$ ). **Equation [2]** is based on extensive experimental analysis, because no exact solution of the Navier–Stokes equation can be given for turbulent pipe flow.

The dimensionless  $Re$  is commonly used to characterize the nature of fluid flow. For liquid flow through pipes,  $Re$  is defined according to **eqn [3]**.<sup>12</sup>

$$Re = \frac{uL}{\nu} = \frac{u\rho L}{\mu} \quad [3]$$

where  $u$  is the average fluid velocity in the pipe ( $\text{m s}^{-1}$ ),  $L$ , the characteristic length (for pipe flow the diameter,  $d$ , of the pipe) (m), and  $\nu$ , the kinematic viscosity of flowing fluid ( $\text{m}^2 \text{s}^{-1}$ ), which can be expressed as the ratio of the hydrodynamic viscosity  $\mu$  (Pa s) and the density  $\rho$  ( $\text{kg m}^{-3}$ ).

From the  $Re$ , the flow regime can be derived. For Newtonian liquids, pipe flow is in the:

- developed laminar flow regime, if  $Re < 2300$ ;
- transition (buffer) flow regime, if  $2300 < Re < 4000$ ;
- turbulent flow regime, if  $Re > 4000$ .

In flow systems with real liquids, energy losses occur as a result of friction at the solid wall and due to eddies (vortices) in the near-wall region. In the laminar flow regime, the pressure loss in a pipe or channel is proportional to the average flow velocity,  $u$ , and can be quantified according to the Hagen–Poiseuille equation (**eqn [4]**).<sup>13</sup>

$$\frac{\Delta p}{l} = 32\mu u \frac{1}{d^2} \quad [4]$$

where  $\Delta p$  is the pressure loss,  $l$  is the tube or channel length, and  $d$  is the characteristic diameter. However, in technical systems, the surface roughness has to be considered with a tube friction factor  $\lambda$  (**eqn [5]**),

which depends on both the surface roughness and the flow regime ( $Re$ ).<sup>13</sup>

$$\Delta p = \lambda \frac{l}{d} \frac{u^2}{2} \rho \quad [5]$$

For laminar flow ( $Re < 2300$ ), the friction factor is a direct function of the  $Re$  (**eqn [6]**):

$$\lambda = \frac{64}{Re} \quad [6]$$

In the case of turbulent flow, the friction factor is strongly dependent on the  $Re$ , and  $\Delta p$  will increase proportional to  $u^2$ . For  $2300 \leq Re \leq 10^5$ , the following relationship was found by Blasius for smooth surfaces (**eqn [7]**):

$$\lambda = \frac{0.3164}{Re^{1/4}} \quad [7]$$

In the case of small  $Re$ , the thickness of the boundary layer may be sufficient to cover all roughness peaks. The pressure loss will be slightly greater than in the case of smooth walls. However, it occurs according to the same physical laws relevant to the laminar region. With increasing  $Re$ , the boundary layer becomes thinner and thinner, and the roughness elements penetrate through the boundary layer into the main flow stream resulting in considerable drag and pressure loss. Thus, with increasing flow velocity, the pressure loss becomes more dependent on the surface roughness. At high roughness, the viscous forces in the near-wall boundary layer become negligible.

Regardless of the multitude of roughness forms and their distribution, a relative roughness,  $\varepsilon$ , is defined according to **eqn [8]**:

$$\varepsilon = \frac{K}{d} \quad [8]$$

where  $K$  is the average height of all roughness peaks. **Equation [8]** also indicates that wall effects decrease with increasing pipe diameter. In the case of fully developed flow, the friction factor  $\lambda$  becomes

independent of the  $Re$  and can be calculated according to eqn [9] (Prandtl, Karman).<sup>14</sup>

$$\lambda^{-1/2} = 2 \log \frac{d}{K} + 1.14 \quad [9]$$

These equations are empirical in nature. However, they clearly indicate that pressure losses in pipes strongly depend on the flow velocity (more general: the  $Re$ ) and on fluid–wall interactions, which depend on the surface roughness on the solid side and on the nature of the boundary layer on the fluid side. In the following section, the nature of the boundary layer is looked at in more detail.

### 2.13.2.2 The Boundary Layer

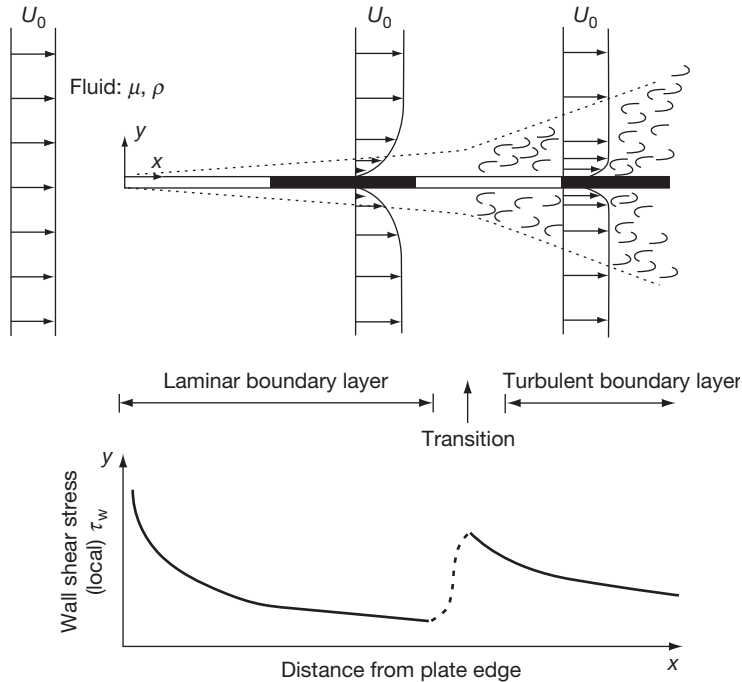

The boundary layer is a near-wall region with non-uniform flow in a small layer between the bulk flow and the solid wall. This small layer is not constant over a greater length, but develops gradually in the flow direction. All friction effects occur within this layer, while in the bulk region, the flow is friction-free in the ideal case.

The development of the boundary layer is shown schematically in Figure 2. A thin plate is hit by a free flow with the velocity  $U_0$ . A boundary layer starts forming at the plate surface. The gradient of flow

velocity,  $u(y)$  – with  $y$  giving the distance from the plate surface – changes over the length of the plate. The thickness of the boundary layer increases with the distance,  $x$ , from the front of the plate. The Prandtl's boundary layer,  $\delta_{Pr}$ , is defined as the distance  $y$  where the local flow velocity is only 1% smaller than the bulk velocity (eqn [10]).<sup>15</sup>

$$\delta_{Pr} = \mathcal{N}(U_{y=0.99U_0}) \quad [10]$$

The flow in the boundary layer can be laminar or turbulent. In a small region after the leading edge of the plate where the boundary layer thickness is still small, the flow regime is laminar. With increasing thickness of the boundary layer along the plate, the boundary layer becomes increasingly unstable and turbulences are formed. The region where laminar flow changes to turbulent flow is called the transition region. The thickness of the boundary layer increases step-like along the plate. The time-averaged velocity profiles are shown in Figure 2. In the laminar region, the wall shear stresses,  $\tau_w$ , decrease up to the transition region. There wall shear stresses  $\tau_w$  increase spontaneously because the ratio between the change of flow velocity,  $du$ , and the distance,  $dy$ , from the plate increases spontaneously. However,  $\tau_w$  decreases gradually along the plate length,  $x$ .

**Figure 2** Boundary layer along a thin plate.

The properties of the boundary layer can be characterized by local  $Re$ , which are related either to the layer thickness,  $\delta_{Pr}$ , or to the distance,  $x$ , from the front of the plate (eqns [11] and [12]).<sup>15</sup>

$$Re_{\delta_{Pr}} = \frac{U_0 \delta_{Pr}}{\mu} \quad [11]$$

$$Re_x = \frac{U_0 x}{\mu} \quad [12]$$

*Laminar boundary layer:* The layer thickness,  $\delta_{Pr}$ , increases with the distance from the leading edge of the plate and decreases with the flow velocity,  $U_0$ . This can be expressed by the Blasius equation (eqn [13]).<sup>15</sup>

$$\delta_{Pr} = 5.0 \sqrt{\frac{\nu x}{U_0}} = \frac{5.0x}{\sqrt{Re_x}} \quad [13]$$

The wall shear stress,  $\tau_w$ , is directly related to the gradient of the flow velocity (eqn [14]).

$$\tau_w = \mu \left( \frac{dU}{dy} \right)_{y=0} = 0.332 \mu \frac{U_0}{x} \sqrt{Re_x} \quad [14]$$

where  $\mu$  is the hydrodynamic viscosity (Pa s).

*Turbulent boundary layer:* The turbulent boundary layer exhibits a much more complex structure than the laminar boundary layer. The major part of the boundary layer consists of the turbulent zone (Figure 3) with a chaotic turbulence activity and permanently changing flow pattern. The turbulent zone is again divided into an outer zone and an inner zone (often called buffer zone). Only in the inner zone are viscous effects encountered.<sup>16,17</sup>

Close to the wall, in the inner zone (Figure 3), the fluctuations are damped, resulting in a viscous sublayer with laminar flow profile. In general, the flow pattern in the viscous sublayer is taken as quasi-static. However, it has been shown experimentally that turbulences in the outer and, specifically, in the buffer zone can affect the flow situation in the viscous sublayer, causing fluctuations of the thickness and the flow pattern in the viscous sublayer.<sup>18–20</sup>

The three regions of the turbulent boundary layer can be mathematically resolved using the normalized (dimensionless) flow velocity,  $u^+$  (eqn [15]), and the normalized (dimensionless) wall distance,  $y^+$  (eqn [16]).

$$u^+ = \frac{u}{u_x} \quad [15]$$

$u$  is mean velocity in turbulent boundary layer ( $\text{m s}^{-1}$ )

$$y^+ = \frac{y u_x}{\nu} \quad [16]$$

where  $y$  is distance from the wall (m),  $u_x = \sqrt{(\tau_w/\rho)}$  is shear velocity ( $\text{m s}^{-1}$ ),  $\nu$ , the kinematic viscosity ( $\text{m}^2 \text{s}^{-1}$ ),  $\tau_w$ , the wall shear stress ( $\text{N m}^{-2}$  or Pa), and  $\rho$ , the fluid density ( $\text{kg m}^{-3}$ ).

The velocity distribution in the viscous sublayer ( $y^+ < 5$ ), in the buffer region ( $5 < y^+ < 30-40$ ), and the outer turbulent zone ( $30-40 < y^+ < 100$ ) can be calculated according to the equations given in the semilogarithmic plot in Figure 4.<sup>18</sup>

The local flow velocity in the viscous sublayer can be calculated according to eqn [17]:

$$u = \frac{\tau_w}{\mu} y \quad [17]$$

Figure 3 Turbulent boundary layer.

**Figure 4** Structure of the turbulent boundary layer and distance-related velocity distribution. Reproduced from Davies, J. T. In *Turbulence Phenomena*; Academic Press: New York, 1972; Chapter 2, pp 121–143.

### 2.13.2.3 Flow Patterns

The interaction intensity between flowing media and solid walls depends on the number of phases and on the magnitude and relative ratio of the superficial velocities of each phase involved. (The superficial velocity is calculated separately for each phase assuming that no other phase is present). The easiest-to-describe flow pattern is the undisturbed, developed single phase flow. Much more complicated and more dangerous, with respect to flow-induced localized corrosion, (FILC) is the disturbed single phase flow as encountered downstream of weld beads, pipe fittings, valves, orifice plates, at pipe joints, upsets, bends, tees, elbows, or tube inlets of heat exchangers. The hydrodynamic description becomes even more challenging in the case of two-phase flow (liquid–liquid, liquid–gas, liquid–solid) and multiphase flow (liquid–liquid–gas, liquid–liquid–solid, liquid–gas–solid, liquid–liquid–gas–solid) in horizontal, inclined, or vertical flow systems, not to mention additional conditions of surface or flow directional disturbances. **Figures 5–7** give examples of mixed phase flow patterns.<sup>9,21,22</sup>

What makes exact hydrodynamic descriptions so difficult is the fact that a multitude of fluid–wall interactions can take place, including mass transfer, heat transfer, fluctuating shear stresses parallel to the surface, fluctuating energy densities (fluctuating pressures) perpendicular to the surface, particle impact (erosion), and near-wall gas bubble collapse

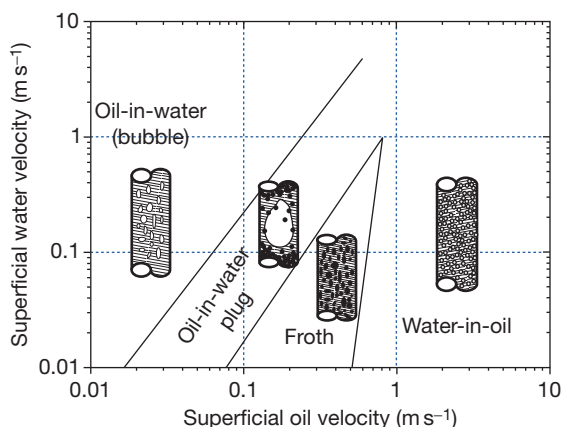

**Figure 5** Flow patterns in horizontal liquid–gas pipe flow. W.; Aziz, K. *The Flow of Complex Mixtures in Pipes*; Van Nostrand Reinhold: New York, 1972; pp 324, 326, 506.

(cavitation) (**Figure 8**). Besides these kinds of interactions, the nature of the wall (surface roughness, hardness, ductility, and fracture toughness, presence of protective layers like films, coatings, or scales) plays a significant role. This is the reason why predictive mathematical models in flow-assisted corrosion are available only for relatively simple flow systems.

### 2.13.3 Corrosion Aspects

Flow can enhance uniform corrosion or initiate and propagate localized corrosion. The first case is mostly encountered when the material's surface is bare

(i.e., scale free) or is covered with a very porous and thus nonprotective scale. This case will be described as flow-enhanced corrosion (FEC). In contrast the acronym FILC will be used to describe flow-induced localized corrosion generally found under corrosion conditions when more or less protective scales cover the material's surface and are destructed by flow effects.<sup>23–26</sup>

#### 2.13.3.1 Scale-free Surfaces

Under free corrosion conditions, the corrosion rate is flow dependent when the rest potential,  $U_R$ , is in the potential range of the mass transport (diffusion)-controlled region of the cathodic partial current density–potential curve  $j^-$  (Figure 9).  $U_{(Me)}^*$  and  $U_{(CA)}^*$  are the equilibrium potential of the metal–metal ion redox reaction and the cathodic redox reaction, respectively. The corrosion current density,  $j_c$ , is then equal to the diffusion current density,  $j_D$ , of the cathodic partial current density–potential curve  $j^-$ , and  $j_D$  depends on the flow, according to the Fick's law (eqn [18]).<sup>27</sup>

$$j_D = \frac{zFD\Delta c}{d_N} \quad [18]$$

where  $D$  is the diffusion coefficient of the cathodically active species ( $\text{m}^2 \text{s}^{-1}$ ),  $z$ , the number of charges exchanged in the cathodic reaction,  $F$ , Faraday's constant ( $96\,485 \text{ C mol}^{-1}$ ),  $d_N$ , the Nernst diffusion layer thickness (m), and  $\Delta c$ , the concentration gradient of the cathodically active species between the bulk solution ( $c_{\text{bulk}}$ ) and the electrode surface ( $c^*$ ). Under diffusion controlled conditions,  $c^*$  is equal to zero (Figure 10).

In laminar flow regimes,  $d_N$  ranges between 1 and  $100 \mu\text{m}$  and depends on the bulk flow velocity,  $u_0$ , according to eqn [19], where  $n$  can take values between 0.5 and 1.<sup>17</sup>

$$d_N = \frac{1}{u_0^n} \quad [19]$$

The hydrodynamic layers next to the metal surface will exhibit a transition from pure diffusion and migration immediately next to the surface to a convection-dominated region further away from the surface. It is mathematically convenient to consider a simplified model of the interface that consists of a layer in which only diffusion and migration occur, known as the Nernst diffusion layer, in direct contact with bulk solution, which has a constant composition. The thickness,  $d_N$ , of the Nernst diffusion layer is

**Figure 8** Fluid-wall interactions in flow systems. Reproduced from Heitz, E. In *Flow-Induced Corrosion: Fundamental Studies and Industry Experience*; Kennelley, K. J., Hausler, R. H., Silverman, D. C., Eds.; NACE International: Houston, TX, 1991; pp 1:1–1:29.

**Figure 9** Current density–potential plot for diffusion controlled metal corrosion.

**Figure 10** Concentration gradients in Nernst diffusion layer.

proportional to the thickness of the Prandtl boundary layer,  $\delta_{Pr}$  (eqn [20]).

$$d_N \sim \left(\frac{D}{\nu}\right)^{1/3} \delta_{Pr} \quad [20]$$

For aqueous solutions with kinematic viscosities,  $\nu$ , in the order of  $10^{-2} \text{ cm}^2 \text{ s}^{-1}$  and diffusion coefficients in the order of  $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ ,  $d_N$  ranges in the order of 10% of the Prandtl boundary layer.

The ratio between the kinematic viscosity and the diffusion coefficient is also called Schmidt number,  $Sc$  (eqn [21]).<sup>17</sup>

$$Sc = \frac{\nu}{D} = \left(\frac{u_0 l}{D}\right) / \left(\frac{u_0 l}{\nu}\right) = \frac{Pe}{Re} \quad [21]$$

$Pe$  is the Peclet number ( $=u_0 l/D$ ). When the flow becomes turbulent (high  $Re$ , rough surfaces), the transport conditions become more complicated and can be expressed only semiquantitatively. For  $Sc$  in the order of  $10^3$ , the diffusion boundary layer thickness is of the order of 1/6 of the thickness of the viscous sublayer. Thus, the diffusion boundary layer reacts directly to changes in the thickness of the viscous sublayer.

For turbulent flow, a general equation exists for mass transport correlations at different flow patterns, based on the dimensionless parameters  $Re$ ,  $Sc$ , and  $Sh$  (eqn [22]).<sup>28</sup>

$$Sh = aSc^b Re^c \quad [22]$$

The Sherwood number,  $Sh$ , describes the ratio of total mass transport to mass transport by molecular diffusion (eqn [23]).<sup>29</sup>

$$Sh = \frac{kL}{D} \quad [23]$$

where  $k = D/d_N$  is the mass transport coefficient ( $\text{m s}^{-1}$ ), and  $L$ , the characteristic length (m). The constants  $a$ ,  $b$  and  $c$  in eqn [22] are given in Table 1 for different flow devices.

### 2.13.3.2 Scale-Covered Surfaces

At scale-covered metal surfaces, molecular pore diffusion becomes the rate-determining step (Figure 11). This depends, of course, on the pore size and density.

In general, the corrosion rate becomes nearly independent of flow under the assumption that the thickness or the existence of the scale is not influenced by the flowing medium, for example, due to enhanced dissolution or cracking and subsequent spalling. The major concentration gradient of electro-active species (transported to or from the metal surface at the bottom of the pores) occurs in the pores.<sup>9,30</sup> The flow intensity at the scale-covered surface will influence only the convective diffusion of electro-active species in the Prandtl boundary layer to the entrance of the pores, which generally results in only a small concentration gradient (Figure 11).

The mass transport in the laminar Prandtl boundary layer,  $d_{Pr}$ , and in the pores of the scale can be described by Fick's law (eqns [24] and [25]):

$$m_{Pr} = D_{Pr} \frac{c_{bulk} - c_s}{d_{Pr}} \quad (\text{Diffusion in Prandtl layer}) \quad [24]$$

$$m_s = D_s \frac{c_s - c_0}{d_s} \quad (\text{Pore diffusion}) \quad [25]$$

**Table 1** Mass transport relationships for important flow systems

Flow system	Power law $Sh = aSc^b Re^c$	Range of validity	Characteristic length and $Re$
Free rotated disc			
Laminar flow	$0.60Sc^{1/3}Re^{1/2}$	$10^2 < Re < 10^5$	$L = r, Re = \frac{\omega r^2}{\nu}$
Turbulent flow	$0.011Sc^{1/3}Re^{0.87}$	$Re > 10^6$	
Rotated disc in front of wall			
Laminar flow	$17.3Sc^{1/3}Re^{0.34}$	$9 \times 10^4 < Re < 6 \times 10^5$	$L = r, Re = \frac{\omega r^2}{\nu}$
Turbulent flow	$0.05Sc^{1/3}Re^{0.78}$	$Re > 6 \times 10^5$	
Free rotated cylinder

**Figure 11** (a) Corrosion process on scale-covered metal surfaces and (b) concentration gradient of electro-active species from the bulk solution to the metal surface.

where  $m_{Pr}$  is the mass transport rate in the Prandtl boundary layer ( $\text{mol m}^{-2} \text{s}^{-1}$ );  $m_s$  is the mass transport rate in the pores ( $\text{mol m}^{-2} \text{s}^{-1}$ );  $D$  is the diffusion coefficient of the electro-active species (i) under convective diffusion in the Prandtl layer ( $D_{Pr}$ ) and (ii) in the pores of the scale ( $D_s$ );  $c$ , the concentration ( $\text{mol m}^{-3}$ ) of the electro-active species (i) in the bulk ( $c_{\text{bulk}}$ ), (ii) at the entrance of the pores ( $c_s$ ), and (iii) at the metal surface ( $c_0$ ); and  $d_s$  is the thickness of the layer (m).

The kinetics of corrosion processes at scale-covered materials results from a combination of the following simplified partial processes:

1. Transport of corrosive species to the scale (eqn [26])<sup>9</sup>:

$$v_1 = k_1(c_{\text{bulk}} - c_s) \quad [26]$$

This process is controlled by the combination of convection and diffusion. The coefficient  $k_1$  is flow-dependent.

2. Transport of electro-active species through the pores of the scale (eqn [27]):

$$v_2 = k_2(c_{\text{bulk}} - c_s) \quad [27]$$

This process is mainly controlled by diffusion. The coefficient  $k_2$  is strongly dependent on the pore structure of the scale but is not flow-dependent.

3. Interface reaction (eqn [28]):

$$v_3 = k_3 c_0 \quad [28]$$

The coefficient  $k_3$  is potential-dependent, but not flow-dependent. Under conditions of stationary mass transport rate, the following equations are valid (eqns [29] and [30]):

$$c_{\text{bulk}} = (c_{\text{bulk}} - c_s) + (c_s - c_0) + c_0 \quad [29]$$

or

$$v = v_1 + v_2 + v_3 \quad [30]$$

Regarding eqns [26]–[28] and the assumptions in eqns [29] and [30], the following relationships will result (eqns [31] and [32]):

$$c_{\text{bulk}} = \frac{v}{k_1} + \frac{v}{k_2} + \frac{v}{k_3} \quad [31]$$

with

$$v = v_1 + v_2 + v_3 = \frac{c_{\text{bulk}}}{(1/k_1) + (1/k_2) + (1/k_3)} \quad [32]$$

where  $v$  is the corrosion rate ( $\text{g m}^{-2} \text{h}$ );  $k_1$ ,  $k_2$ ,  $k_3$  are coefficients, where only  $k_1$  is flow-dependent.  $k_2$  and  $k_3$  depend on the pore structure (size, density). As the scale is growing and the porosity is decreasing, that is,  $k_2 \rightarrow 0$ , the flow velocity effect will decrease.

The rate of scale formation,  $\Phi_{\text{scale}}$ , is proportional to the mass conversion rate (corrosion rate) according to eqn [33]:

$$\Phi_{\text{scale}} = K_1 v \quad [33]$$

The rate of scale destruction is influenced by the flow intensity, which is expressed mostly in terms of wall shear stress,  $\tau_w$  (eqn [34]):

$$\Phi_{\text{destruct}} = K_2 \tau_w^a \quad [34]$$

The proportionality factor,  $K_2$ , is mainly influenced by the binding forces between the particles (e.g., crystallites) forming the scale and the adhesion between scale and base material. The exponent,  $a$ , relates to the flow pattern and the contribution of erosion and cavitation. For a dynamic equilibrium ( $\Phi_{\text{scale}} = \Phi_{\text{destruct}}$ ), it follows that

$$K_1 v = K_2 \tau_w^a \quad [35]$$

$$v = \frac{K_2}{K_1} \tau_w^a = K_3 \tau_w^a \quad [36]$$

These equations (eqns [35] and [36]) describe the relation between the mass conversion rate (corrosion rate) and the flow intensity, expressed in terms of wall shear stress,  $\tau_w$ . The proportionality factor,  $K_3$ , describes the density of the scale, its porosity, the binding forces between the particles forming the scale, and finally its fracture stress.<sup>30–32</sup>

### 2.13.3.2.1 Scale destruction

For each corrosion system, a critical flow intensity  $I_{\text{crit}}$  can be identified above which the scale is destroyed and its protectiveness is lost (Figure 12). The corrosion rate increases abruptly and finally becomes purely mass transport controlled according to the boundary conditions of a scale-free system.<sup>25,30</sup>

The classic mechanism of scale destruction above the critical flow intensity is sketched in Figure 13. It is assumed that near-wall microturbulences cause local thinning of the scale, which locally becomes porous and finally is completely carried away by the flow. Once a scale-free, unprotected local surface area has formed, the local flow intensity prevents the

**Figure 12** Dependence of corrosion rate on flow intensity.

reformation of the protective scale, and local penetrations start producing the characteristic pattern of FILC. While it is possible that the scale is destroyed particle by particle and crystal by crystal during interaction with the flowing media, more recent observations revealed that scales of oxides, carbonates, phosphates, and sulfides rather crack and spall.<sup>33,34</sup> Figures 14 and 15 give examples of iron carbonate and iron sulfide scales from which parts of the scales experienced cracking and spalling. The fracture stresses of such scales have been measured<sup>33–35</sup> and range in the order of 75–720 MPa for iron carbonate scale from CO<sub>2</sub> corrosion of steel and 50–150 MPa for iron sulfides from H<sub>2</sub>S corrosion of steel. The fracture stresses are influenced by the porosity and thickness of the scale and increase dramatically when formed in the presence of effective corrosion inhibitors.<sup>36,37</sup> Figure 16 shows the failure mode diagram of corrosion-produced iron carbonate scales in the absence and presence of corrosion inhibitor. The corrosion inhibitor decreases the scale thickness, and hence, increases the critical fracture strain. The data were used to evaluate the surface fracture stress of iron carbonates (Figure 17).<sup>34,38</sup>

In view of the magnitude of the fracture stresses and adhesion strengths measured for corrosion product scales,<sup>34,35,38</sup> which number in the MPa range (Table 2), it appears difficult to understand that wall shear stresses in the range of 10–100 Pa (technical systems) or at maximum up to 10<sup>3</sup>–10<sup>4</sup> Pa (extreme local flow intensities) can cause cracking and spalling of scales.

As it is clearly proven that flow-induced fluid dynamic forces can destroy protective layers, it is necessary to define such forces, which obviously act not parallel to the surface (as the wall shear stress) but rather perpendicular to the surface (Figure 18). This hydrodynamic force perpendicular to the wall shall be called hydrodynamic energy density,  $E_D$  (Pa). For the initiation of FILC, the hydrodynamic energy density

**Figure 16** Failure mode diagram of FeCO<sub>3</sub> (data from 4-point-bent-tests). Reproduced from Schmitt, G.; Mueller, M.; Papenfuss, M.; Strobel-Effertz, E. must be, at least locally, equal or greater than the fracture stress of the scales,  $\sigma_B$  (Pa) (eqn [37]).

$$E_D \geq \sigma_B \quad [37]$$

While the wall shear stress,  $\tau_w$  (Pa), has been clearly defined (eqn [14]) and measured for a long time, the hydrodynamic energy density,  $E_D$  (Pa), has been defined only recently<sup>39,40</sup> during investigations,

aiming at identifying the interaction energy of singly near-wall turbulence elements via microelectrochemical flow measurements.

This approach used the L  veque equation<sup>41</sup>(eqn [38]), which correlates the wall shear stress with the diffusion current density of a tracer redox system at a microelectrode (diameter 15–200   m) under defined flow conditions.

$$\tau_w = k[j_D]^3 \quad [38]$$

with

$$k = \frac{\mu}{0.81^3 z^3 c_0 l^2 b^3 D^2} \quad [39]$$

where  $k$  is a constant depending on the dynamic viscosity,  $\mu$  (Pa s), of the electro-active species, the number  $z$  of electrons exchanged in the tracer redox system, the concentration,  $c_0$  (mol m<sup>−3</sup>), and diffusion coefficient,  $D$  (m<sup>2</sup> s<sup>−1</sup>), of the redox system, and the geometry of the microelectrode: the length,  $l$  (m), and the width,  $b$  (m).

The measured flow dependent parameter is  $j_D$  (A m<sup>−2</sup>), the diffusion current density of the mass transport-controlled redox reaction. Most commonly, the hexacyano-ferrate(II/III) redox system (eqn [40]) is used as tracer redox system in such measurements, because of its simple one-electron transfer and known system parameters.

Under turbulent flow conditions, the diffusion-controlled current densities,  $j_D(t)$ , measured at microelectrodes are fluctuating with time (Figure 19) due to fluctuations in the Nernst diffusion layer, which is caused by turbulence elements disturbing the viscous sublayer of the turbulent boundary layer. In order to evaluate the information contained in the noise of the diffusion current densities, the noise data (after subtraction of the DC part) have been subjected to a Wavelet transform, which yields the signal amplitudes in the frequency and time domain (Figure 20).

For each time resolution, an amplitude/frequency spectrum is obtained. It appears that at different times

**Figure 18** Interaction of hydrodynamic forces with scales.

**Figure 19** Evaluation of diffusion controlled current density noises.

**Figure 20** Linear wavelet transform of current noise signal.

different amplitude fluctuations are encountered. Furthermore, no discrete frequency spectra are observed even at very high time resolution. Based on this, broad frequency range simulations have been performed with the aim of investigating whether the frequency spectra obtained can provoke high-intensity singularities, which significantly exceed the general noise level. The simulation was performed according to the algorithm expressed in eqn [41].<sup>39,40</sup>

$$j_D(t) = \sum_{\omega} A(\omega) \sin(\omega t)_{t_0} \quad [41]$$

At an arbitrarily chosen time (e.g., at the time 0.5 s, Figure 20), the corresponding amplitude/frequency spectrum is obtained (Figure 21). If all amplitudes at all frequencies in the selected frequency range are added for this specific time according to eqn [41], a singularity arises that represents the same singular

**Figure 21** Polynomial fitting (fourth grade) for time cut in Wavelet data.

situation when oceanic ‘freak waves’ (Rogue Waves)<sup>42,43</sup> are formed. In this case, a group of surface waves with different wave heights (amplitudes) travels in the same direction, but with different velocities. When all waves of this group are phased in for a single moment, that is, when they meet at the same time, a single wave is formed that piles up orders of magnitude higher than the average height of the group of waves. This singularity contains the power of all waves included, and the volume elements of this singular wave contain the highest energy density possible under these conditions.

In order to apply the same algorithm on the amplitude/frequency profile chosen in the example according to Figure 21, the amplitude/frequency function is fitted with a polynomial equation, which is inserted in eqn [41] for the amplitude  $A$ . The summing-up range shall include the relevant frequency range (e.g., 1–2500 Hz; see Figure 21). Within a unit time of 1 s, the summing-up procedure will be repeated in very small time steps, for example,  $1/250\,000$  s.<sup>39,40</sup>

The results of this calculation are presented in Figure 22. A singularity is found in the time range close to  $t = 1$  s, the amplitude of which exceeds the general noise level by orders of magnitude. Taking into account that the amplitudes represent diffusion current densities, the maximum in Figure 22 represents a fictive maximum diffusion current density in the order of  $500.000 \text{ mA cm}^{-2}$ . This phenomenon repeats at all unit time intervals.

The physical meaning of this maximum current density (called ‘freak current density’) is that, at the time of this ‘freak’ event, volume elements of the ‘freak wave’ in a near-wall turbulence element close

to the viscous sublayer is accelerated perpendicular toward the solid surface (Figure 23), reaching through the viscous sublayer down to the solid. If a microelectrode is present on the surface, the viscous sublayer, and hence, the Nernst diffusion layer is deformed for a very short time (in the range of milliseconds) to thicknesses that allow extreme high mass transport rates.

The energy density,  $E_D$ , of a freak wave volume element accelerated toward the surface can be

**Figure 22** Simulation of the noise current density based on Wavelet transform data. Phasing-in of amplitudes in the unit time region. Reproduced from Schmitt, G.; Werner, C.; Bakalli, M. In *Evaluation of Local Energy Densities in Disturbed Flow: A New Approach to Characterize Inhibitor Efficiencies to Mitigate Erosion Corrosion*, Proceedings of European Conference, EUROCORR'2004, Nice, France, Sept 12–16, 2004; European Federation of Corrosion, The Institute of Materials, London, 2004.

**Figure 23** Model of freak wave impact on protective scales. Reproduced from Schmitt, G.; Werner, C.; Bakalli, M. In *Evaluation of Local Energy Densities in Disturbed Flow: A New Approach to Characterize Inhibitor Efficiencies to Mitigate Erosion Corrosion*, Proceedings of European Conference, EUROCORR'2004, Nice, France, Sept 12–16, 2004; European Federation of Corrosion, The Institute of Materials, London, 2004.

expressed according to classic wave dynamics with eqn [42].<sup>44</sup>

$$w = \frac{dE}{dV} = \frac{1}{2} \rho A^2 \omega^2 \quad [42]$$

where  $w$  is energy density (Pa),  $\rho$  is density ( $\text{kg m}^{-3}$ ),  $A$  is wave amplitude (m), and  $\omega$  is wave frequency ( $\text{s}^{-1}$ ). Both energy density and wall shear stress have the unit Pascal. It is, therefore, assumed that the same relation used in the L  veque equation can be used to calculate the 'freak' energy density,  $E_D^F$ , from the freak current density,  $j_D^F$  (eqn [43]):

$$w_F = \tau_F = E_D^F = k_{\text{red/ox}} [j_D^F(t)]^3 \quad [43]$$

or by using eqn [41]:

$$\tau_F = E_D^F = k_{\text{red/ox}} \left( \sum_{\omega} A(\omega) \sin(\omega t_F) \right)^3 \quad [44]$$

$k_{\text{red/ox}}$  is a calibration factor which relates to the redox system used for measuring the diffusion-controlled current noise fluctuations. For the hexacyanoferrate redox system, this calibration factor has been evaluated to<sup>45</sup>:

$$k_{\text{red/ox}} = 2.14 \times 10^{-8} \quad (\text{Nm}^4 \text{A}^{-3}) \quad [45]$$

A freak amplitude of  $500\,000 \text{ mA cm}^{-2}$  (Figure 22) would then amount to a freak energy density (FED) of  $\sim 3 \text{ GPa}$ , which is by far enough to crack any protective scale. For comparison, the fracture stress of iron carbonate single crystals have been estimated to range in the order of  $1.4 \text{ GPa}$ , while fracture stresses of iron carbonate layers from  $\text{CO}_2$  corrosion of steel have been measured to range in the order of  $0.075\text{--}0.72 \text{ GPa}$ .<sup>34</sup>

Thus, the critical flow intensity, which can cause cracking and subsequent spalling of protective scales, and therefore, will initiate FILC that can be determined with eqn [43] using mass transfer-controlled current density noise data from flush-mounted microelectrodes with subsequent Wavelet transform treatment.

Based on this FED model, the effect of additives (inhibitors, drag reducers/flow improvers) on the prevention of FILC can easily be understood. Assuming that the critical fracture stress of an iron carbonate scale is  $200 \text{ MPa}$  (Figure 24), a FED of about  $3000 \text{ MPa}$  encountered under given flow conditions in a  $\text{CO}_2$  corrosion system is by far enough to crack the scale. Addition of  $1 \text{ mM C12-quat(PEGmod)}$  (polyethylenglycol-modified C12-quaternary alkyl-ammonium halide) reduces the FED significantly

**Figure 24** Effect of additives on freak energy densities. Reproduced from Schmitt, G.; Werner, C.; Bakalli, M. In *Fluid Mechanical Interactions of Turbulent Flowing Liquids with the Wall – Revisited with a New Electrochemical Tool*, Corrosion'2005; NACE International: Houston, TX, 2005; Paper no. 344.

**Figure 25** Effect of flow velocity and C14-Quat concentration on maximum (freak) energy density in single phase flow. Reproduced from Schmitt, G.; Bakalli, M. In *Quantification of Maximum Energy Densities Between Flowing Liquids and Solid Walls – Effect of Flow Improving Additives*, Proceedings of European Conference, EUROCORR'2006, Maastricht, The Netherlands, Sept. 24–28, 2006; European Federation of Corrosion, The Institute of Materials: London, 2006.

under otherwise constant conditions, and cannot, however, reduce it below the fracture stress of the scale. Only with 1 mM C14-quat (tetradecyltrimethylammonium bromide) could the freak energy density be reduced significantly below the fracture stresses of the scale, and thus, the onset of FILC be prevented.<sup>39,40</sup>

The effect of C14-Quat concentrations at different jet nozzle velocities on the maximum (freak)

energy densities encountered in aqueous liquids with kinematic viscosities in the order of 1 mPa s is very significant and consistent and supports the FED approach.

#### 2.13.3.2.2 Corrosion intensity after scale destruction

After flow-induced local destruction of protective scales, layers, or films, the surface of the base material

is attacked like a bare metal surface, depending on the environmental conditions, that is, depending on the relative contributions of the corrosion and the erosion part to the rate of materials loss. These contributions can be estimated from the exponent  $a$  in eqn [46], which aims to relate the mass loss rate,  $w_{\text{er}}$ , in erosion corrosion to the bulk flow velocity,  $u_b$ .<sup>4</sup>

$$w_{\text{er}} \propto u_b^a \quad [46]$$

For mass control of the corrosion reaction, the exponent  $a$  is 0.33 for laminar flow and 0.8–1.0 for developed turbulent flow. It is zero for charge transfer (activation) control and somewhere between 0 and 1 under mixed control. The exponent  $a$  is 1 also for materials with passive films under activation/repassivation control. If erosive effects are contributing,  $a$  is  $>1$ , for example, 2–3 in the case of solid particle impingement or even 5–8 in the case of cavitation attack or liquid droplet impingement in high-speed gas flow.

While the bulk flow velocity in full bore flow or superficial flow velocities of the phases in question are readily measured and controlled, it is appreciated that, specifically, in disturbed flow, the flow characteristics in the direct vicinity of the wall are much more important than the bulk flow situation. Therefore, the trend is increasing to evaluate at least the existing wall shear stresses. However, bulk parameters are still used to characterize a given flow system.

### 2.13.3.3 Tools for Investigating Flow-Assisted Corrosion

A great variety of laboratory tools is available for investigating flow-assisted corrosion.<sup>46</sup> Lab tools used include (Figures 26–28)<sup>28,47–50</sup>:

- rotated probes;
- pipes and channels; and
- jet impingement.

Rotated probes with axial symmetry include the free-rotated disc, the disc in front of a wall, the free-rotated cylinder, and the coaxial cylinder (Figure 26).<sup>28</sup> Another set-up of rotated probes is the rotated cage (Figure 27), which contains coupons arranged between holders in such a way that the outer surface of the coupons forms parts of the surfaces of a rotating cylinder.<sup>48</sup>

The industrially prevalent type of flow exists in pipes. Therefore, flow studies with tubes/pipes and channels (Figure 26) are performed in those cases where a direct correlation with real flow situations in pipes is needed.

A very powerful tool is the impinging jet (Figure 28), which is specifically suitable to investigate susceptibilities of materials to FILC under severe flow intensities and to study the efficiency of corrosion mitigation, for example, the application of corrosion inhibitors under such conditions. A newly

**Figure 26** Standardized tools to investigate flow-assisted corrosion. Reproduced from DIN 50920, Corrosion of Metals, Part I; In *Corrosion Testing in Flowing Liquids; General* (in German); Beuth Verlag: Berlin, Germany, 1985.

**Figure 27** Rotated cage arrangement. Reproduced from Schmitt, G.; Bruckhoff, W. In *Relevance of Laboratory Experiments for Investigation and Mitigation of Flow Induced Corrosion in Gas Production*, Corrosion'88; NACE International: Houston, TX, 1988; Paper no. 357.

developed modification is the gas-pulsed impinging jet (Figure 29), which can simulate the damaging effect of slug flow without using a slug flow loop.<sup>46</sup>

Mass transport relationships available for the different experimental tools are listed in Table 1. The merits and limitations of each tool are discussed in the literature.<sup>46</sup> Here, the authors clearly differentiate between corrosion experiments (where corrosion rates are directly calculated from time and surface related mass loss measurements and where localized corrosion can be observed by visual inspection of the corroded specimens) and electrochemical experiments, which may give information on corrosion rates as well, but should rather be used for mechanistic investigations, specifically to determine the nature of rate-determining steps in corrosion mechanisms.

**Figure 29** Gas-pulsed impinging jet. Reproduced from Schmitt, G.; Bakalli, M. In *A Critical Review of Measuring Techniques for Corrosion Rates under Flow Conditions*, Corrosion'2006; NACE International: Houston, TX, 2006; Paper no. 593.

### 2.13.3.3.1 Rotating disc electrode

The rotating disc electrode (RDE) is preferentially used to investigate mass transport phenomena in laminar flow conditions. According to the Levich equation (eqn [47]),<sup>51</sup> the mass transport rate,  $w$ , in a mass transport-controlled system is constant over the disk surface and proportional to the square root of the angular velocity,  $\omega$ , of the disc:

$$w = k\sqrt{\omega} \quad [47]$$

where  $w$  is the mass transport rate, for example, expressed in terms of mass loss rates ( $\text{g m}^{-2} \text{h}^{-1}$ ),  $\omega$  is the angular velocity in radian per second, and  $k$  is the constant, containing the diffusion coefficient,  $D$ , of the rate-determining diffusing species ( $\text{m}^2 \text{s}^{-1}$ ), its concentration,  $C_{\text{bulk}}$ , in the bulk solution ( $\text{mol m}^{-3}$ ), and the kinematic viscosity,  $\nu$ , of the solution investigated ( $\text{m}^2 \text{s}^{-1}$ ) (eqn [48]).

$$k = 0.6205 D^{2/3} \nu^{-1/6} C_{\text{bulk}} \quad [48]$$

The mass transport rate can also be studied electrochemically. In the case of mass transport control, the diffusion-limited current density measured at a rotated disc electrode is proportional to the square root of the angular velocity,  $\omega$  (eqn [49]):

$$j_D = 0.6205 n F D^{0.66} \nu^{-0.167} \omega^{0.5} C_{\text{bulk}} \quad [49]$$

with the number of electrons  $n$  exchanged in the specific electrode reaction,  $F$  ( $96485 \text{ C mol}^{-1}$ ), and the other parameters as defined earlier.

A graph of  $j_D$  versus  $\sqrt{\omega}$  or  $w$  versus  $\sqrt{\omega}$  (Figure 30) should give a straight line going through the origin if the electrode reaction in question is purely

**Figure 30** Levich plot for diffusion controlled and mixed controlled corrosion rate at rotated disc.

diffusion controlled. If the straight line cuts the ordinate according to the equation  $w = a + k\sqrt{\omega}$ , there are either experimental problems (e.g., shaft wobbling, formation of vortices, entrainment of gas bubbles, etc.) or there is an additional electrode reaction involved that is not diffusion limited. From the slope of the straight line in the  $j_D$  versus  $\sqrt{\omega}$  diagram, the diffusion coefficient of the species determining the electrode reaction can be measured very accurately (eqn [49]). The flow pattern at the surface of the rotated disc can be described in terms of dimensionless parameters (Table 1).

#### 2.13.3.3.2 Rotating cylinder electrode

The rotating cylinder electrode (RCE) has the advantage that the complete flow regime from laminar to turbulent can be tested in the same arrangement. Three flow regimes can be differentiated<sup>52,53</sup>:

1. Laminar flow at low rotational speeds of the cylinder (the velocity profile is tangential).
2. Laminar flow superimposed with some turbulent vortices in radial and axial motion above a critical Taylor number ( $Ta = Re[(r_o - r_i)/r_i]$ , where  $Ta$  is dimensionless Taylor number,  $Re$  is Reynolds number,  $r_o$  is outer cylinder radius (static),  $r_i$  is inner cylinder radius (rotating)).
3. Fully turbulent flow above critical  $Re$ .

The transition from laminar to turbulent flow is  $\sim 200$ . Below this critical  $Re$ , the  $Sb$  is constant ( $Sb = 37$ ) and independent of  $Re$ .<sup>54</sup> At  $Re > 200$ , that is, in the turbulent region, the following dimensionless

equation can be used for the system rotating inner cylinder/static outer cylinder (eqn [50])<sup>55</sup>:

$$Sb = 0.00791 Re^{0.7} Sc^{0.356} \quad [50]$$

This equation correlates with data from mass transfer, heat transfer, and friction measurements at cylinders rotating in liquids. The flow intensity at the cylinder wall can be calculated from eqn [51]<sup>56</sup>:

$$\tau_w = 0.0791 Re^{-0.3} \rho r^2 \omega^2 \quad [51]$$

where  $\tau_w$  is the wall shear stress (Pa),  $\rho$  is the solution density ( $\text{kg m}^{-3}$ ),  $r$  is the cylinder radius (m), and  $\omega$  is the rotational speed ( $\text{s}^{-1}$ ).

Corrosion rate at a rotating cylinder is correlated with wall shear stresses using eqn [52].

$$w = a\tau^b \quad [52]$$

where  $w$  is the corrosion rate ( $\text{mm a}^{-1}$ ),  $\tau$  is the wall shear stress (Pa), and  $a$  and  $b$  are constants depending on solution parameters, chemistry, and corrosion product film and require definition.

#### 2.13.3.3.3 Rotating cage

The rotating cage (Figure 27) is commonly used to screen the susceptibility of materials to FILC and to evaluate corrosion inhibitors for their efficiency to prevent initiation of FILC. Due to the many experimental advantages and the successful use of rotated cage data in service, attempts have been made to quantify the flow intensities encountered at coupons rotated in the rotated cage. Equation [53] was developed as an approximation to estimate the wall shear stress at coupons in the rotated cage<sup>57,58</sup>:

$$\tau_{RC} = 0.0791 Re_{RC}^{-0.3} \rho r_{RC}^2 \omega^{2.3} \quad [53]$$

where  $\tau_{RC}$  is the wall shear stress in rotated cage (Pa),  $Re_{RC}$  is the Reynolds number of rotated cage ( $Re_{RC} = \omega r_{RC}^2 / \nu$ ),  $r_{RC}$  is the radius of the rotated cage (m),  $\rho$  is the solution density ( $\text{kg m}^{-3}$ ), and  $\omega$  is the rotational speed ( $\text{s}^{-1}$ ).

This equation is valid only for a certain geometry of the rotated cage with a certain number of coupons in a certain position. Comparison of critical wall shear stresses obtained from both rotated cage and impinging jet experiments for initiation of FILC in different corrosion systems revealed that the critical wall shear stresses calculated according to eqn [53] are about a factor of 2 higher than the values received via eqn [56] for the impinging jet.<sup>59</sup>

### 2.13.3.3.4 Pipe and channel flow

Flow experiments in tubes (pipes) or channels are rated as most service-related and most predictive, because the flow pattern in pipes and channels is encountered in technical plants and is well defined by equations for mass, heat, and momentum transfer. In the lab, pipe and channel flow experiments are generally performed in flow loops. The corrosion-relevant flow intensity at pipe or channel walls is best defined by the wall shear stress,  $\tau_w$ , which can be measured as a pressure drop  $\Delta P$  along a given length  $\Delta L$  of the pipe with a diameter  $d$  (eqn [54])<sup>13,15</sup>:

$$\tau_w = \left( \frac{\Delta P}{\Delta L} \right) \left( \frac{d}{4} \right) \quad [54]$$

The wall shear stress can also be measured electrochemically at microelectrodes flush mounted in pipe walls using the Léveque Equation (eqn [38]).<sup>41</sup>

For a microelectrode with disc-shaped electrode surface (diameter 15–60  $\mu\text{m}$ ) located in the region of highest turbulence of an impinging jet with a hexacyanoferrate (II/III) solution, a factor  $k = 3 \times 10^{-8} \text{ N m}^4 \text{ A}^{-3}$  (eqn [38]) was obtained.<sup>39,40</sup> This value is given here for orientation on its range of magnitude. The microelectrode approach offers the advantage of measuring local wall shear stresses also at sites of disturbed flow (at obstacles, steps, grooves, etc.). Microelectrodes with diameters in the range of the size of microturbulence elements (e.g.,  $\ll 100 \mu\text{m}$ ) allow the mapping of local wall shear stresses at surfaces with high lateral resolution.

The microelectrode approach was successfully used to quantify local and maximum fluid–wall interactions under slug flow intensities<sup>40,60</sup> expressed in terms of Froude numbers. The Froude number ( $Fr$ ) is defined according to eqn [55].<sup>61</sup>

$$Fr = \frac{u_t - u_f}{\sqrt{g \cdot h_{\text{eff}}}} \quad [55]$$

where  $u_t$  is the translational velocity of the slug front ( $\text{m s}^{-1}$ ),  $u_f$  is the average velocity of the liquid film ( $\text{m s}^{-1}$ ),  $g$  is the acceleration due to gravity ( $\text{m s}^{-2}$ ), and  $h_{\text{eff}}$  is the effective height of the liquid film (m). The higher the  $Fr$ , the higher the slug flow intensity.

### 2.13.3.3.5 Impinging jet

The impinging jet, specifically, the submerged impinging single phase jet (Figure 28), has proved its usefulness to investigate flow effects in corrosion systems, specifically, the initiation of FILC. The flow pattern at

the impinging surface has been extensively studied and several detailed mathematical expressions of the hydrodynamics are available.<sup>62,63</sup> On the impinging surface, three hydrodynamic regions can be differentiated (Figure 28): the stagnation region (region A), a region with high turbulence intensities (region B), and the wall jet region (region C). For region B, the wall shear stress can be calculated according to eqn [56]<sup>47,63</sup>:

$$\tau_w = 0.0447 \cdot \rho \cdot u_0^2 \cdot Re^{-0.182} \left( \frac{x}{d} \right)^{-2} \quad [56]$$

where  $\tau_w$  is the wall shear stress (Pa),  $\rho$  is the fluid density ( $\text{kg m}^{-3}$ ),  $d$  is the inner diameter of the jet nozzle (m),  $u_0$  is the fluid velocity at the front of the jet nozzle ( $\text{m s}^{-1}$ ),  $x$  is the radial distance from the jet nozzle center line (m),  $Re$  is based on the dimensions of the jet ( $Re = u_0 d / \nu$ ), and  $\nu$  is the kinematic viscosity ( $\text{m}^2 \text{ s}^{-1}$ ). With microelectrodes flush mounted into the impinging surface, local wall shear stresses can be measured using the Léveque equation (eqn [38]). The impinging jet is commonly used to test the efficiencies of additives (inhibitors, flow improvers) for preventing FILC.

A modification of the impinging single phase jet is the gas-pulsed jet, which has been developed to test under flow intensities exceeding slug flow conditions. Figure 31 shows the wavelet transform plots of the time-related frequency/amplitude distributions obtained at microelectrodes impinging with a gas pulsed jet (Figure 29)<sup>50,64</sup> at a constant superficial liquid velocity,  $v_{\text{SL}}$ , of  $12 \text{ m s}^{-1}$  (at the jet nozzle) and two different superficial gas velocities,  $v_{\text{SG}}$  (Figure 31(a):  $16 \text{ m s}^{-1}$  and Figure 31(b):  $22.3 \text{ m s}^{-1}$ ) at 1 gas pulse per second with a duration of 50 ms. The gas-pulsed impingement under conditions according to Figure 31(b) yielded responses with considerable intensities in a frequency range ( $>1000 \text{ Hz}$ ) clearly exceeding the typical range encountered in a moving slug flow at  $Fr = 13$  (Figure 31(c)). The gas-pulsed impinging jet is a new versatile and small-scale experimental device to test flow-improving additives and the efficiency of corrosion inhibitors under slug flow conditions.

Equations for determining wall shear stresses and limiting current densities in different experimental set-ups are collected in Table 3.

### 2.13.3.3.6 Maximum local flow intensities

In most technical corrosion systems, the materials applied are exposed to the flowing media with a scale-covered surface. This makes scale cracking

**Figure 31** Flow intensities at surface impinged with the gas-pulsed jet (a, b) and treated with a moving horizontal slug (c). Reproduced from Schmitt, G.; Al-Janabi, Y. T.; Plagemann, P.; Bakalli, M. *Can the Gas-Pulsed Impinging Jet Simulate Slug Flow?*, Proceedings of European Conference, EUROCORR'2003, Budapest, Hungary, Sept 28–Oct 2, 2003; European Federation of Corrosion, The Institute of Materials: London, 2003.

and spalling the prevailing mechanism of FILC initiation. The evaluation of critical flow intensities, therefore, needs the selection of the appropriate experimental tools, which at acceptable experimental flow conditions can produce maximum (local) flow energy densities high enough to overcome the fracture stresses of the scales involved. (Editor's note: The theory presented here is based on a hypothesis to explain the creation of mechanical forces that are sufficient to fracture and remove protective layers and scales. While the hypothesis is plausible and provides an explanation for a number of experimental flow results, further work is needed to confirm this hypothesis and to understand fully the mechanism of scale removal.)

The maximum (freak) energy densities encountered in different flow systems have been quantified by microelectrochemical current noise measurements

and subsequent Wavelet transform analysis using the algorithm outlined elsewhere in this volume. The maximum local flow intensities achieved with different experimental flow devices under single-phase and two-phase flow conditions are compared in [Figure 32](#) with a logarithmic scale for liquids with viscosities in the range of 0.8–1.1 mPa s (e.g., aqueous solutions with moderate concentrations of dissolved solids).<sup>39,40,45,67</sup>

The maximum energy densities encountered under slug flow conditions range from 3 MPa (Froude number 5:  $u_{SL} = 0.5 \text{ m s}^{-1}$ ;  $u_{SG} = 2.0 \text{ m s}^{-1}$ ) to 30 MPa (Froude number 13:  $u_{SL} = 1.5 \text{ m s}^{-1}$ ;  $u_{SG} = 6.0 \text{ m s}^{-1}$ ).<sup>39,40</sup> With the gas-pulsed impinging jet energy densities can easily be achieved, which are 60–110 times higher than under severe moving slug flow conditions ( $Fr = 13$ ).<sup>67</sup> It appears that the superficial liquid velocity ( $u_{SL}$ ) is more important for achieving high maximum (freak) energy densities than the superficial gas

In *Fluid Mechanical Interactions of Turbulent Flowing Liquids with the Wall – Revisited with a New Electrochemical Tool*, Corrosion'2005; NACE International: Houston, TX, 2005; Paper no. 344; Schmitt, G.; Bakalli, M. In *Quantification of Maximum Energy Densities Between Flowing Liquids and Solid Walls – Effect of Flow Improving Additives*, Proceedings of European Conference, EUROCORR'2006, Maastricht, The Netherlands, Sept. 24–28, 2006, European Federation of Corrosion, The Institute of Materials: London, 2006; Nakoryakov, V. E.; Kashinsky, O. N.; Kozmenko, B. K. In *Measuring Techniques in Gas-Liquid Flows*; Delhay, J. M., Cognet, C., Eds.; Springer: Heidelberg, 1984; pp 695–721.

velocity. In the gas-pulsed jet approach, the gas pulse was injected once per second with duration of 50 ms. This indicates that the gas pulsed impinging jet can be used as an alternative experimental tool to the space-, time-, and cost-consuming slug flow loop, at least for screening purposes.

In single phase flow, the jet impingement allows the coverage of a wide range of maximum energy

densities under easily achieved flow conditions. Thus, with the usual jet cell geometries, jet nozzle velocities of 3 or 12 m s<sup>-1</sup> create maximum energy densities of about 28 and 940 MPa, respectively.<sup>45</sup> The flow intensities produced in the rotating cage are comparatively smaller. At angular velocities as low as 10.5 rad s<sup>-1</sup> (equivalent to 100 rpm), the maximum energy density reaches only 0.14 MPa. However, even at 100.5 rad s<sup>-1</sup>

(equivalent to 1000 rpm), the maximum local flow intensities amount only to 44 MPa. In view of the fracture stresses and adherence forces generally encountered for scales formed under corrosion conditions (Figure 33), the rotating cage finds its application for the quantification of critical flow conditions in the moderate range of flow intensities. The impinging jet and, even more, the gas-pulsed impinging jet can be used up to extreme fracture stresses of scales. Figure 33 demonstrates once more the importance of the FED approach for the understanding of the initiation step of FILC.

### 2.13.3.4 Erosion Corrosion and Cavitation Corrosion

Although FILC can occur already in single phase liquid flow, localized material attack very often is encountered in two-phase and multiphase flow. Thus, solid particle impact in a liquid or gas phase, liquid droplet impact in a gas phase, gas bubble impact in a liquid phase, and near-wall vapor bubble collapse in a liquid phase (Figure 8) can damage material surfaces with a mechanical and a corrosive contribution. While the material attack

In *Quantification of Maximum Energy Densities Between Flowing Liquids and Solid Walls – Effect of Flow Improving Additives*, Proceedings of European Conference, EUROCORR'2006, Maastricht, The Netherlands, Sept. 24–28, 2006, European Federation of Corrosion, The Institute of Materials: London, 2006; Nakoryakov, V. E.; Kashinsky, O. N.; Kozmenko, B. K. In *Measuring Techniques in Gas–Liquid Flows*; Delhay, J. M., Cagnet, C., Eds.; Springer: Heidelberg, 1984; pp 695–721.

produced by the first three cases of impingement is generally termed erosion or – in the case of corrosive contributions – erosion corrosion, the material damage by near-wall vapor bubble collapse is called cavitation or – in the case of corrosive contributions – cavitation corrosion. Typical examples of erosion corrosion and cavitation corrosion are given in [Figures 34–36](#).

#### 2.13.3.4.1 Solid particle impingement

Solid particles entrained in a flowing liquid can damage a material surface if they impact with a kinetic energy above critical values, which are material specific and relate to the nature and properties of scales, layers, or films, and the base material. The effective kinetic impact energy of the particle depends on the impact velocity,  $u_p$ , the impact angle, and the particle density, size, shape, relative hardness, and micro-roughness. At low effective impact energies, the particle impact destroys only the scales, layers, or films and activates the surface for corrosion. In this case, the kinetics of reformation of the scales, layers, or films ('repassivation') play an essential role for the final corrosion rate. At higher impact energies, the particles may penetrate into the surface of the material and can even cut out solid particles.

**Figure 34** Erosion corrosion and cavitation corrosion at pump impeller (cast duplex stainless steel).

The rate of erosion corrosion,  $w_{er}$ , is, therefore, proportional to the kinetic energy of the impinging particle, that is, proportional to  $u_p^2$ , and the frequency of impacts, that is, proportional to  $u_p$ . Thus, in a first approximation, the rate of erosion corrosion correlates with the particle velocity in a cubic relationship (eqn [57])<sup>68</sup>:

$$W_{er} \propto u_p^3 \quad [57]$$

Under conditions where the effective particle impact energy is above the critical value for scale, layer, or film destruction, but below the critical value for eroding the base material, the rate of erosion corrosion, is generally, directly proportional to the particle velocity and its concentration.<sup>68</sup> Velocity exponents up to 3 are encountered under conditions of base material erosion.

Impact angle of particles in nondisturbed turbulent pipe flow are generally below  $5^\circ$ . However, under

**Figure 35** Erosion corrosion and cavitation corrosion at pump impeller (cast carbon steel).

**Figure 36** Erosion corrosion at flow disturbance in copper pipe for cold tap water.

conditions of disturbed flow, a wide range of impact angle will be encountered. Erosion corrosion of brittle materials by slurries increases, with the particle impact angle reaching a maximum at an angle of  $90^\circ$ . Ductile materials develop erosion corrosion maxima at angles in the range of  $15^\circ$ – $50^\circ$ .<sup>23</sup> Erosive attack drops dramatically when the impacting particles are softer than the base material.

#### 2.13.3.4.2 Liquid droplet impingement

Liquid droplets entrained with fast-flowing gases or vapors can impinge on the surface with energy densities far higher than single phase or multiphase liquid flows. The result is the destruction of scales, layers, or films and, in severe cases, also the deformation of the surface to form discrete sharp-edged pits, which are gradually deepened by continued droplet impacts. Under such conditions, the mechanical part of erosion corrosion dominates, as in cavitation corrosion. However, the overall mass loss is still influenced by the kinetics of repassivation processes, which can be enhanced by appropriate alloying (e.g., increase of Mo content in stainless steels) or by the addition of powerful corrosion inhibitors. Liquid droplet impingement is encountered in low-pressure steam turbine blades operated with wet steam or in aircraft and helicopter rotors frequently operated in rain.

#### 2.13.3.4.3 Gas bubble impingement

Gas bubbles entrained with fast-flowing fluids can damage protective scales, layers, or films locally when the impact energy is high enough. This may happen specifically at sites of disturbed flow, for example, at the inlets of heat exchanger tubes where air bubbles can develop a substantial radial velocity component. The morphology of the damage starts with isolated ‘horseshoes,’ which grow together and finally cause considerable roughening of the surface.

#### 2.13.3.4.4 Cavitation

When gas bubbles implode in very close vicinity to the surface, they form very small liquid ‘microjets,’ which impact on the surface with flow velocities of up to  $100 \text{ m s}^{-1}$  (Figure 37). This is enough to destroy protective layers and deform the material in a way that particles of the base material are loosened and carried away. Cavitation bubbles with diameters  $<1 \text{ mm}$  can form at sites where, due to local turbulence conditions (e.g., at sharp diameter changes in pipes, edges of propellers, turbine blades or pump impellers), the hydrostatic pressure decreases for a

**Figure 37** Collapse (implosion) of cavitation bubble with jet formation.

very short time below the saturation vapor pressure of the liquid. The collapse occurs downstream in higher pressure regions. Vibrating solid surfaces, for example, the cooling water side of diesel engine cylinder liners or the shell-side of heat exchanger tubing, may also experience cavitation attack.

In cavitation corrosion, the mechanical contribution is by far dominating. However, the corrosion contribution should not be neglected, because it can be influenced significantly by enhancing the repassivation kinetics and by using appropriate corrosion inhibitors. Even the mechanical impact can be reduced by flow improving additives.

#### 2.13.3.5 Corrosion Control

The basic methods for controlling flow-assisted corrosion and/or FILC include design modifications, changing of flow regime, and the improvement of the fluid mechanical properties of the flowing medium.

##### 2.13.3.5.1 Fluid mechanics and design

The majority of failures by flow-assisted corrosion or FILC are based on poor design and ignorance of fluid mechanical principles. Therefore, flow related design is the most important corrosion control method. The design should primarily aim at reducing the flow velocity. The importance of this measure can be derived from eqn [46], which relates the corrosion rate to the flow velocity. For mass-controlled corrosion reactions, the exponent of the velocity term is 0.33 for laminar, but up to 1 for turbulent flow. For flow conditions causing destruction of protective scales, the exponent can reach values up to 3 and amount to 8 for cavitation conditions.

Rules of thumb have been empirically developed in different industries to estimate critical flow velocities, which should not be exceeded. One rule that was originally established in power generation for preventing FILC in pipes for wet steam has been adapted by the oil and gas industry as API-RP 14E,<sup>69,70</sup> where the critical flow velocity is inversely

proportional to the square root of the medium density (eqn [58]):

$$u_{\text{crit}} = C(\text{Density})^{-1/2} \quad [58]$$

With a proportionality factor  $C$  of 7.6 and the density given in ( $\text{kg m}^{-3}$ ), the critical flow velocity is obtained in ( $\text{m s}^{-1}$ ). The proportionality factor is 100 (for inhibited systems 150–200) if the density is given in  $\text{lbs ft}^{-3}$ . The critical velocity is then obtained in  $\text{ft s}^{-1}$ . For liquid flows, the proportionality factor of 100 is very conservative; for gas flows, it underestimates the potential for erosion. This holds also for information contained in BS EN ISO 13703:2001 developed for offshore applications.<sup>71</sup>

For plumbing systems in tap water distribution, critical flow velocities are given, for example, for steel ( $4 \text{ m s}^{-1}$ ) and copper ( $2 \text{ m s}^{-1}$ ). Many critical parameters have been worked out for materials in seawater application. Maximum design velocities for CuNi10 (UNS C70600) piping for seawater have been related to pipe diameters based on measurements of critical wall shear stresses (Figure 38).<sup>72</sup> For CuNi30 (UNS C71500)  $4.5 \text{ m s}^{-1}$  and CuNi10 (UNS C70600)  $3.6 \text{ m s}^{-1}$  have been accepted industrially as critical flow velocities in large piping for unpolluted seawater.<sup>72</sup> Critical flow parameters for copper alloy tubing are collected in Table 4.<sup>7,10</sup> In the chemical industry, the general (conservative) design rule is to prevent flow velocities above  $1.5 \text{ m s}^{-1}$ .

Proper design should also avoid abrupt changes in the flow system geometry, for example, steps, grooves, solder beads, rectangular elbows, tees, etc. Experience shows that flow disturbances as small as corrosion pits (even smaller than 1 mm) or burrings

on cut ends of tubing may create sufficient turbulence to destroy protective layers and initiate FILC. Erosion corrosion at heat exchanger tube-inlets can be solved by plastic inserts.

### 2.13.3.5.2 Materials selection

Selection of materials with higher resistance to flow-assisted corrosion is another option for corrosion control by design. Flow resistance is often related to the hardness of the material. Figure 39 gives an example for copper and copper alloys in tap water.<sup>73</sup> The erosion corrosion performance of valve materials in seawater is compared in Figure 40.<sup>74</sup> Material selection is also helpful for mitigating cavitation corrosion. Figure 41 presents different materials with respect to the relative material loss by cavitation.<sup>75</sup>

The variety of materials is great for application in fast-flowing media, for example, ferritic, ferritic-austenitic (duplex) and austenitic steels, NiCr alloys and titanium and its alloys (Figure 42).<sup>6</sup> To combat erosion corrosion by fluids containing solid particles, successful developments have been made with cast alloys and duplex steels. However, materials should not be selected only by their flow resistance, but also with consideration of susceptibility to localized corrosion such as pitting, which is a common problem with stainless steels and also nickel-base alloys, specifically in slow-flowing and stagnant media and under deposits. In these cases, decreasing the flow rate may not be the appropriate remedy for corrosion control.

In special applications, surface protection by metallic, organic, or ceramic coatings can be a solution to prevent FILC. The adhesion and mechanical stability of such protective layers is important.

### 2.13.3.5.3 Environment control

Environment control includes influencing the fluid chemistry and the fluid hydrodynamics (flow improvement).

Reducing the corrosivity of the flow system by removal or exclusion of corrosive components is surely an efficient step to control flow-assisted corrosion. An example would be the removal of oxygen from seawater or adjustment of pH. However, this is often not possible or not feasible. In these cases, the selection of appropriate additives can be very effective. Corrosion inhibitors are known to foster the formation of more flow-resistant protective scales with higher fracture stress, and hence, improve the resistance to FILC.

**Figure 38** Maximum design velocities of piping for seawater. Reproduced from Efrid, K. D. *Corrosion* **1973**, 33(1), 3–8.

**Figure 39** Maximum allowable flow velocity for water in copper and copper alloy piping. Reproduced from Sick, H. *Werks. Korros.* **1972**, 23, 12.

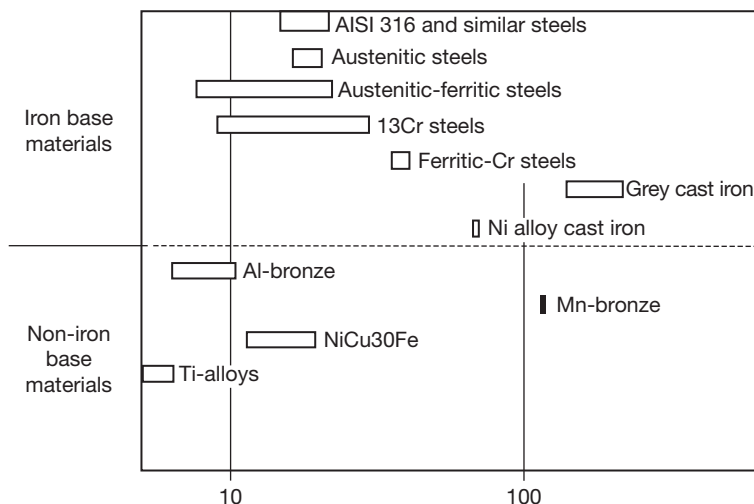

The efficiency of corrosion inhibitors in flowing media depends on local flow intensities (**Figure 43(a)**). Above critical flow intensities, inhibitors lose their efficiency. Under these conditions, the material surface is subject to FILC. Critical flow intensities for FILC initiation can also depend on the inhibitor concentration (**Figure 43(b)**). This depends on the chemical structure of the active inhibitor compounds and the formulation of inhibitor packages.<sup>76</sup> Economical inhibition of corrosion under turbulent flow conditions needs functional additives that inhibit under high critical flow intensities at low concentrations.

In any case, the inhibitor concentration should be adjusted to the flow intensity and to a given target corrosion rate. With increasing flow intensity, an increase of the inhibitor concentration is likely to be necessary to reduce the corrosion rate below the target value. Failure prevention must be the primary goal for the selection of the type and the concentration of a functional additive.

However, reduction of the corrosion rate is not the only effect of corrosion inhibitors. They may also influence the flow dynamic property of the fluid, that is, by acting as a drag reducer, or in other words, as a flow improver.<sup>37</sup> There is literally no flow process that cannot be influenced by adding such 'drag-reducing agents' (DRA): frictional resistance of turbulent pipe and boundary layer flow is diminished; local energy losses at flow obstacles are reduced; the periodic formation of vortices in the flow field behind a cylinder experiences a shift to lower frequencies; resistance to laminar flow in porous media is increased; sedimentation and flocculation processes become accelerated; the efficiency of hydraulic transport of solids rises; the onset of cavitation starts at higher flow velocities and causes less damage to materials; flow noise becomes less intense. DRA have been suggested in various technical fields, for example, in industrial water distribution systems to reduce the pumping energy, in oil and gas transport as well as in hydraulic transport of solids (e.g., coal), to increase (e.g., double) the capacity of pipelines, in waste water pipe networks to reduce the residence time of waste water in sewers at peak loads, in ship technology to reduce the flow friction in order to increase the speed of ships (e.g., cut in half the

**Figure 41** Cavitation resistance of different pump materials. Reproduced from Weber, J. VDI-Report No. 365, 1980, pp 73.

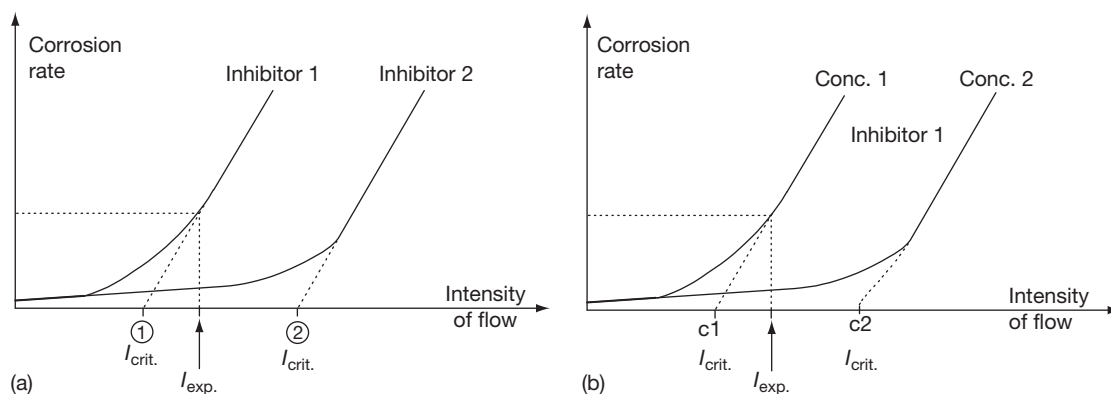

drag of a super-tanker), in fire fighting technology to reduce the jet spray and increase the throwing distance of the water jet from the fire-hose nozzle (e.g. by a factor of 5).

DRAs include polymers like polyethylenoxides, polyacrylamides, guar gum, sodium carboxymethylcelluloses, and other polymers, which are, however, only effective at mole masses  $>10^6$  Da. Besides polymers, complex detergent mixtures, for example, an

equimolar mixture of cetyltrimethylammonium bromide (CTAB) and 1-naphthole, and other quaternary ammonium salts can exhibit drag-reducing activity.<sup>8,37,77</sup> However, these compounds become DRAs only above the critical micelle concentration (cmc). It is assumed that near-wall turbulence elements interact with the DRA under energy dissipation into internal energy by viscous actions. For polymers, this implies shear-induced

**Figure 42** Materials performance in media with high levels of hydrogen sulfide and low pH. Reproduced from Weber, J. *Br. Corros. J.* **1992**, 27(3), 193–199.

**Figure 43** Effect of flow intensity on corrosion inhibitor performance.

coil-stretch actions, for surface active compounds, shear-induced deformation of supramolecular micelle structures.

The effect of additives in two-phase flow systems was observed, for example, in brine/hydrocarbon mixtures under annular mist flow conditions with a superficial gas velocity of  $18.4 \text{ m s}^{-1}$  and a superficial liquid velocity of  $0.015 \text{ m s}^{-1}$  at  $80^\circ\text{C}$ , and  $\text{CO}_2$  partial pressures of up to 25 bar (Figure 44).<sup>8</sup> In the presence of  $1 \text{ mmol l}^{-1}$  additive, the relationship between wall shear stress and gas density ( $\text{CO}_2$  gas pressure) significantly deviated from the linear relationship measured in the absence of additives. The highest effect was measured at higher  $\text{CO}_2$  pressures

in the presence of higher molecular alkylamines. The wall shear stress could be reduced by a factor of 5, thus reducing the risk of FILC.<sup>8</sup>

The drag-reducing efficiency of C14-quat (tetradecyl-trimethylammonium bromide) in single phase flow and under slug flow conditions is exemplified in Figure 25 and Figure 45, respectively. The interaction intensity between aqueous liquids and the solid wall is, here, characterized by the maximum (freak) energy density of the flow system.

#### 2.13.3.5.4 Cathodic protection

Cathodic protection could also be used for corrosion control in flow systems. The application is, however,

limited because it is technically often difficult to provide the appropriate protection current inside pipes, valves, or pumps, by auxiliary anodes due to difficult geometries. Furthermore, evolution of hydrogen might be a problem, for example, in the case of titanium and other materials that could experience hydrogen embrittlement.

**Figure 44** Flow improving effect of additives in annular mist flow loop under CO<sub>2</sub> corrosion conditions. Reproduced from Schmitt, G.; Bücken, W. In *Effect of Corrosion Inhibitors and Surfactants on the Fluid Dynamic Properties of Multiphase Annular Mist Flow in CO<sub>2</sub> Corrosion Systems*, Corrosion'92; NACE International: Houston, TX, 1992; Paper no. 6.

### 2.13.3.5.5 Control of solid particle impingement attack

Control measures can include appropriate material selection, application of functional additives, and flow adjustment. Material selection often ends up with carbon steel because of its relatively low price. Erosive metal loss is then generally compensated by higher wall thicknesses. Stainless iron-base alloys exhibit satisfactory erosion corrosion resistance due to fast healing passive layers, but are more costly. The materials listed in Figure 40 in terms of corrosion resistance for valve applications also exhibit good resistance to erosion corrosion. However, material selection has to account also for the concentration and the nature (hardness) of the suspended solids. Criteria are different for flow systems with low concentrations of suspended particles and for slurries with high concentration of solids. High-Cr-Mo alloys with high carbon content (e.g., 20–28% Cr, 2% Mo, 2–2.5% C) have been successfully used for slurries with pH values down to 4. For more corrosive environments, the carbon content should be reduced. For sand and gravel pumps, Ni-hard alloys (4% Ni, 2% Cr) found successful application in the case of mildly corrosive conditions. Also rubber-lined pumps are an option for abrasive slurries (particle size >3 mm).

The literature reports on the excellent performance of Stellite (cast Co alloy) and silicon carbide during the handling of slurries with pumps. Figure 46

**Figure 45** Effect of flow velocity and C14-Quat concentration on the maximum (freak) energy density under slug flow conditions simulated via gas-pulsed impinging jet. Reproduced from Schmitt, G.; Bakalli, M.; Hoerstermeier, M. In *Contribution of Drag Reduction to the Performance of Corrosion Inhibitors in One- and Two-Phase Flow*, Corrosion'2007; NACE International: Houston, TX, 2007; Paper no. 615.

**Figure 46** Normalized erosion resistance of materials relative to 316 SS (HV 170). Reproduced from Heymann, F. J. In *ASM Metals Handbook: Friction, Wear and Lubrication Technology*, Vol. 18; ASM: Metals Park, OH, 1992; pp 221–232.

gives an overview of the erosion resistance of various materials, normalized relative to 316 austenitic stainless steel with a hardness of HV 170.<sup>78</sup> These data relate mainly to impingement and cavitation test results and fit together, because the mechanical part dominates in both failure mechanisms. However, these data should be taken only as a first orientation.

#### 2.13.3.5.6 Control of liquid droplet impingement attack and cavitation

Due to similar effects, failure prevention under conditions of liquid droplet impingement and cavitation can use similar options in material selection and flow control by design. **Figures 41 and 46** show a good orientation for material selection. However, polymeric materials, for example, high-density polyethylene (HDPE) or rubber, could also provide a solution. Flow control of droplet impingement should consider the droplet density (amount of impacting liquid), droplet size, and angle of droplet impact. Design options depend on the technical situation. If feasible, droplets should be removed, for example, by cyclones, or deflected with impingement plates. Guidelines for avoiding cavitation by proper design of pumps, orifices, valves, and elbows, are given in the literature.<sup>79</sup> They primarily aim at changing the hydraulic conditions. For centrifugal pumps, the major design parameter is the pressure difference between the total absolute pressure and the vapor

pressure at the pump suction. Corrosion inhibitors have been successful in reducing cavitation attack in cooling systems of diesel engines. Another option is to use flow-improving additives (superhigh molecular polymers, micellar aggregates).

#### 2.13.3.5.7 Predictive modelling

Computational fluid dynamics (CFD) methods have been successfully applied to predict flow fields and mass transfer rates for various system geometries in single phase and multiphase flow.<sup>80,81</sup> For fluids with entrained solid particles, the CFD procedure includes flow simulation, calculation of particle tracking, and assessment of erosion rates.<sup>81–87</sup> A comparison of results from different CFD approaches with experimental data indicates that CFD is a powerful tool in predicting erosion and erosion corrosion.<sup>86</sup>

**I<sub>peak</sub>** Peak current about I<sub>p</sub> (A)  
**I<sub>lim</sub>** Limiting current (A)  
**i<sub>0</sub>** Maximum current density on fresh metal surface at the start of repassivation (A m<sup>-2</sup>)  
**J** Flux of species (mol s<sup>-1</sup> cm<sup>-2</sup>)  
**k** Dimensionless wear coefficient  
**k<sub>a</sub>** Anodic rate constant  
**k<sub>B</sub>** Rate constant  
**k<sub>d</sub>** Generation rate of wear particles  
**k<sub>1</sub>** Forward reaction rate  
**k<sub>-1</sub>** Backward reaction rate  
**k<sub>m</sub>** Mass-transport coefficient (cm s<sup>-1</sup>)  
**K** Constant  
**K<sub>a</sub>** Proportionality constant  
**K<sub>w</sub>** Proportionality constant  
**K<sub>1</sub>** Constant  
**l** Length of wear track (m)  
**L** Characteristic length or sliding distance (m)  
**L<sub>ox</sub>** Oxide layer thickness (m)  
**m** Mass of oxide removal (kg) or energy exponent  
**M<sub>ox</sub>** Mass of oxide (kg)  
**M<sub>p</sub>** Mass of sand impacting the surface per unit time (kg s<sup>-1</sup>)  
**M<sub>R</sub>** Metal dissolution rate (mol cm<sup>-2</sup> s<sup>-1</sup>)  
**M<sub>w</sub>** Oxide molar mass (g mol<sup>-1</sup>)  
**n** Velocity ratio exponent or bulk concentration exponent or number of contact cycles at a given crack site  
**n<sub>r</sub>** Scratch overpotential (V)

**$N_c$**  Number of critical microcracks on a unit area of the wear surface that are ready to propagate

**$N_r$**  Number of critical microcracks that are ready to propagate to generate wear debris in a reference environment

**$\Delta N_c$**  Increment of the number of critical microcracks due to the presence of corrosion

**$N$**  Number of erodent impacts

**$N_{o,u}$**  Total number of surface sites available

**$N_u$**  Number of moles of oxide formed (mol)

**$p$**  Pressure (Pa)

**$q$**  Charge passed =  $\int I dt$  (C)

**$Q$**  Wear volume loss ( $m^3$ )

**$r_p$**  Particle radius (m)

**$R$**  Universal molar gas constant (= 8.31451  $J K^{-1} mol^{-1}$ )

**$Re$**  Reynolds number

**$R_f$**  Roundness factor for particle (value 0–1)

**$s$**  Total sliding distance (m)

**$S$**  Synergy (mg or  $mg s^{-1}$ )

**$Sc$**  Schmidt number

**$Sh$**  Sherwood number

**$t$**  Time (s)

**$t_c$**  Critical time for crack to propagate a length  $D$  (s)

**$t_0$**  Time to produce a scratch (s)

**$T$**  total wear or erosion loss ( $mg s^{-1}$ )

**$T_s$**  Temperature of the surface ( $^{\circ}C$ )

**$U$**  Free stream velocity or relative sliding velocity ( $m s^{-1}$ )

**$U_{cr}$**  Critical velocity for plastic deformation ( $m s^{-1}$ )

**$U_f$**  Velocity component normal to surface ( $m s^{-1}$ )

**$U_p$**  Particle velocity ( $m s^{-1}$ )

**$\nu^*$**  Friction velocity ( $=\sqrt{(\tau_w/\rho)}$ ) ( $m s^{-1}$ )

**$\nu_e$**  Sliding velocity ( $m s^{-1}$ )

**$V$**  Volume loss ( $m^3$ )

**$V_p$**  Particle volume ( $m^3$ )

**$V_u$**  Erosion rate ( $\mu m^3$  per impact)

**$V_c$**  Material loss due to ‘pure’ corrosion without the effect of mechanical wear ( $m^3$ )

**$V_{cw}$**  Total material loss during corrosion wear due to both corrosion and wear ( $m^3$ )

**$V_w$**  Pure wear loss in otherwise the same environment as in the corrosion wear process but without corrosion ( $m^3$ )

**$V_{wc}$**  Material loss due to wear during corrosion wear ( $m^3$ )

**$W$**  Normal load (N)

**$y$**  Vertical height (m)

**$y^+$**  Dimensionless scale

**$z$**  Number of electrons, average valance, charge on migrating species

**$\alpha$**  Angle of impact ( $^{\circ}$ )

**$\alpha_1$**  Symmetry constant

**$\delta$**  Boundary layer thickness or repassivated oxide thickness (m)

**$\Delta C$**  Change in concentration of species ( $= (C_b - C_0)$ ) (M, mM,  $mol cm^{-3}$ )

**$\Delta C$**  Enhancement of  $C$  due to the presence of erosion ( $mg$  or  $mg s^{-1}$ )

**$\Delta E$**  Synergistic effect or enhanced erosion rate due to corrosion ( $mg$  or  $mg s^{-1}$ )

**$\Delta H$**  Change in hardness (Hv or Pa)

**$\Delta V_c$**  Wear-induced corrosion ( $m^3$ )

**$\Delta V_s$**  Synergistic effect ( $m^3$ )

**$\Delta V_w$**  Corrosion-induced wear ( $m^3$ )

**$\Delta \varphi$**  Potential difference across oxide (V)

**$\epsilon_c$**  Critical plastic strain ( $\mu m m^{-1}$ )

**$\eta$**  Turbulent eddy viscosity (Pa s)

**$\theta$**  Surface coverage fraction

**$\kappa$**  Specific wear rate ( $mm^3 N^{-1} m^{-1}$ )

**$\rho_f$**  Density of fluid ( $kg m^{-3}$ )

**$\rho_{ox}$**  Density of oxide ( $kg m^{-3}$ )

**$\rho_p$**  Density of particle ( $kg m^{-3}$ )

**$\rho_T$**  Density of target material ( $kg m^{-3}$ )

**$\sigma$**  Dynamic plastic flow stress for target ( $N m^{-2}$ )

**$\tau$**  Passive film recovery time (s)

**$\tau_w$**  Wall shear stress ( $N m^{-2}$ )

**$\tau_0$**  Characteristic passivation time of a metal during repassivation from a fresh surface (s)

**$\tau_i$**  Characteristic reaction time for the reaction controlling a corrosion fatigue process (s)

**$\nu$**  Kinematic viscosity ( $m^2 s^{-1}$ )

**$\mu$**  Dynamic viscosity (Pa s) or coefficient of friction

### 2.15.1 Introduction and Definitions

The term ‘tribo’ has origins in the Greek word ‘tribos’ (rubbing), which led to the sciences of lubrication, friction, and wear being called ‘Tribology,’ while the term corrosion has its origins in the medieval Latin word ‘corrodere,’ which means to gnaw through with ‘cor’ meaning intensive force and ‘rodere’ to gnaw.<sup>1</sup> For this chapter, corrosion will be used to relate to surface degradation involving electrochemical and chemical processes. Therefore, the term tribocorrosion refers to the surface degradation mechanisms when mechanical wear and chemical/electrochemical processes interact with each other. Many of the mechano–electrochemical interactions involved in tribocorrosion are time dependent and nonlinear. Recent activity in tribocorrosion research aims at addressing

the need to select or design new surfaces for future equipment as well as minimize the operating costs and extend the life of existing machinery and medical devices. The subject therefore includes the interaction of corrosion and erosion (solids, liquid flow, and droplet impingements or cavitation bubbles), abrasion, adhesion, fretting, and fatigue wear processes. Tribocorrosion is often linked to the synergy or antagonism resulting from the coupling of mechanical and environmental effects. For example, during friction the adhesive dissipation of energy is often influenced by chemical effects.<sup>2</sup> Similarly, stainless steels rely on a 1–10 nm thick passive film for their protection from aggressive and corrosive environments. This film forms essentially instantaneously by reaction with the environment but abrasion can lead to a local rupture or complete removal of the film and permanent deformation of the substrate. This can lead to areas of the substrate being exposed to the aggressive environment and unless repassivation (repair or self-healing) mechanisms reform the passive film to inhibit corrosion processes, accelerated anodic dissolution will occur within these sites.

The subject area does, however, suffer from rather loosely defined terms that sometimes relate to the same processes. Thus, to help readers, the terms used in this chapter and their definitions are given in the following paragraphs, but some overlap between these terms is inevitable.

The term flow-corrosion (sometimes referred to as flow-enhanced corrosion, flow-induced corrosion, or flow-accelerated corrosion (FAC) in some texts) will be used to describe corrosion that occurs on surfaces exposed to laminar or turbulent flow but is unable to disrupt passive surface films or corrosion layers.

Erosion-corrosion will be used where mechanical processes as well as flow effects are acting on the surface. This covers solid particle, liquid droplet, cavitation impingement, and some highly turbulent flows where energetic jetting or impingement flows onto the surface occur and can disrupt surface films or layers. Surface film disruption is by mechanical processes associated with contact stresses, stress wave reinforcement, surface shear stresses or pressure fluctuations generated on the surface through water hammer, dynamic fluid pressures, transverse momentum transfer, etc. These mechanical processes can lead to increased corrosion through electrochemical and chemical processes. Reference is normally made to the critical flow velocity above which erosion-corrosion occurs for specific flow geometries and materials.

Tribocorrosion will be used to cover the much broader area or all wear and corrosion interactions. This will cover, for example, abrasion-corrosion and sliding wear-corrosion. Wear is the term used to cover abrasive, adhesive, oxidative, fretting, fatigue-based processes that are part of mechanically induced surface degradation and material loss mechanisms.

Understanding tribocorrosion processes is important if costs associated with material losses are to be minimized. For example, modern fluid handling and propulsion systems face increasing demands for higher flow rates with the inherent risk of flow-corrosion, and if solids are entrained and impinge on the surface or cavitation occurs near the surface, erosion-corrosion can result and accelerate material loss significantly. This is especially true for industries that transport slurries and other particle-laden fluids in pipes or seawater propulsion systems such as offshore and marine technologies. These industries expend the equivalent of millions of pounds every year to repair erosion-corrosion damage caused by solid particle impingement and cavitation. Typical examples of this kind of material destruction are erosion-corrosion damage to pump impellers (see [Figure 1](#)), propellers, valves, heat exchanger tubes, pneumatic and hydro-transport systems, fluidized bed combustors, and many other types of fluid-handling equipment. The erosion-corrosion data and models published in the open literature aspire to allow informed surface selection for combined erosion and corrosion resistance. They are rarely based on substantive physical understanding and some approaches are simply designed to make numerical modeling easier. The erosion-corrosion data are very patchy and incomplete, and therefore hamper any improvement in the performance of machines in aggressive environments.

**Figure 1** Cavitation-corrosion of a 150 mm diameter bronze centrifugal pump impeller from a swimming pool pump.

Tribocorrosion is also critical to long-term human health and patient mobility. The correct understanding of biotribocorrosion and joint design can offer huge savings for health services and impact on the quality of life. For example, current predictions suggest 268 000 total knee arthroplasty revisions will be required per annum in the United States by 2030 as against 38 000 now.<sup>3</sup> Estimating a cost of \$30k per revision, this implies an additional annual cost of \$6.9 billion at today's costs. Extending joint life through improved tribological design would therefore allow enormous savings in surgery costs besides allowing patients to remain active and in employment. Hence, there is growing need to understand the human cellular and biological reactions to metal ion release generated by tribocorrosion processes as well as surface biotribology performance of these joint implants.

On the positive side, tribocorrosion phenomena can be used as a manufacturing process such as in the chemical–mechanical polishing of silicon wafers. The coupling of mechanical and environmental effects can also create surfaces of specific reaction layers on materials that could inhibit corrosion and/or wear. Examples of this are self-lubricating and/or self-healing surface layers.<sup>4</sup>

The presence of well-adhered oxide surface films or loosely adhered layers of corrosion products and the ability to reform these films and layers are also critical in many engineering applications where control of friction and wear are important in sliding contacts. These contacts involve contact between the high spots on the interacting surfaces due to their roughness after machining or finishing. Therefore, the load on a contact is rarely distributed evenly over the apparent contact area but is rather distributed among high-spot (asperity) contacts between surfaces, often referred to as junctions. The actual contact area between surfaces is therefore the sum of the individual areas of junctions and will likely be proportional to the normal load. Friction and wear generally are developed by interactions between these asperities, which can be

subjected to severe contact stresses that often result in temporary flattening (elastically) or, if yield stresses are exceeded, permanent plastic flow and deformation of the surface. The friction forces are typically lowered when oxide layers are present on asperities compared with asperity contacts between bare metal. For some systems, the friction forces can be modeled by summing the forces associated with adhesive and deformation processes relating to these asperities. Adhesive forces are often related to the shear strength of junctions made between contacting asperities of surfaces in relative motion and relate to the frictional work. The presence of oxide films or corrosion products on these asperities will alter the level of frictional work and the resulting surface temperatures. **Figure 2** illustrates how oxide-filmed asperities may interact during sliding, assuming that the oxides deform with the asperity. The asperities on the two interacting surfaces are represented as idealized cylindrical protrusions (i.e., flattened protrusions), thereby allowing a flat circular contact of radius ' $a_n$ ' in plan view, to visualize the actual contact area evolution as asperities slide over each other.

Unpredictable interactions can result between wear and corrosion when the surfaces in contact have complex, multiple-phase microstructures that can lead to microgalvanic activity and selective phase corrosion (localized attack) as well as wear modes involving wear debris or corrosion products along with the interacting surfaces that can roll or slide within the contact. Examples of such surfaces include composites or surfaces that undergo compositional changes induced by tribological interactions. For instance, the presence of carbides in a metallic surface, typically formed for improved wear resistance, establishes a microcorrosion cell as the carbide is likely to be cathodic with respect to the surrounding metallic matrix. This can result in the preferential anodic dissolution of the metallic matrix close to or at the matrix–carbide interface and thereby accelerate carbide removal from surfaces and reduce the antiwear properties of the surface.

**Figure 2** Schematic of asperity–asperity interactions of a passivated surface.

## 2.15.2 Tribocorrosion Fundamentals

### 2.15.2.1 Factors Affecting Tribocorrosion

The corrosion dependence on material properties is complex within tribocontacts. Reference to the galvanic series (see **Chapter 2.07, Galvanic Corrosion**) is useful to understand the potential differences possible when a depassivated metal is electrically coupled to a passive metal. This potential difference will drive charge transfer within the contact. This charge transfer is likely to be a function of the magnitude of surface degradation by mechanical processes and how this is affected by the material chemistry, the environmental chemistry, the microstructure, mass transport, and the rate and extent of depassivation, should the surface be passivated. The influence of material parameters on wear is discussed in the following section.

#### 2.15.2.1.1 Material parameters and composition

A review of available wear models such as those used in solid particle erosion shows the diversity of material properties that have been included in published predictive wear equations. Meng and Ludema,<sup>5</sup> for example, have reviewed 28 erosion models and found that on average only five parameters are used per equation but in total 33 different parameters, not all material properties, are quoted. These are tabulated in **Table 1**.

Simpler approaches based on a few parameters are still in use and are shown to have wide applicability

and therefore are useful. For example, the main theory for sliding wear of metals is based on the assumption that contact between two surfaces occurs where asperities contact and the local deformation is plastic (see **Figure 2**). The Figure shows the interaction between sliding asperities as one slides over the other; see **Figures 2(a)–2(e)**. The true contact area is therefore given by the summation of individual asperity contact areas and is proportional to the normal load.

The overall wear volume loss,  $Q$ , per unit sliding distance is associated with the detachment of material from the asperity contacts and the volume of each particle of wear debris will relate to the size of the individual asperity contact. Assuming that the debris volume,  $\delta V$ , is proportional to  $a_r^3$  gives the well-known Archard wear law<sup>6</sup>:

$$Q = \frac{kW}{H} \quad [1]$$

The Archard wear law suggests, for a system with constant  $k$ , that the wear rate is directly proportional to load on the contact but inversely proportional to the surface hardness,  $H$ , of the wearing material. It can be written:

$$\kappa = \frac{V}{WL} = \frac{k}{H} \quad [2]$$

where  $\kappa$  is the dimensional specific wear rate (SWR) (typically quoted as  $\text{mm}^3 \text{Nm}^{-1}$  or  $\text{m}^2 \text{N}^{-1}$ ),  $V$  the volume loss,  $W$  the applied load, and  $L$  the sliding distance.

A similar wear equation to the adhesive Archard wear law (eqn [2]) can be derived for abrasion.<sup>7</sup> It is

**Table 1** Parameters selected in wear models<sup>5</sup>

<i>Erodent/abradent</i>	<i>Target</i>	<i>Fluid flow</i>
Density	Density	Impact angle
Hardness	Hardness	Impact angle max. wear
Moment of inertia	Flow stress	Kinetic energy (KE) transfer between particle and target
Roundness	Young's modulus	Temperature
Single mass	Fracture toughness	Corrosivity
Size	Critical plastic strain	
Velocity	Depth of deformation	
Rebound velocity	Incremental strain per impact	
KE of particle	Thermal conductivity	
	Melting temperature	
	Enthalpy of melting	
	Cutting energy	
	Deformation energy	
	Heat capacity	
	Weibull flaw parameter	
	Lamé constant	
	Grain diameter	

also interesting to note that models developed for predicting current from depassivated surfaces show a  $(W/H)^{1/2}$  dependence, as discussed later in [Section 2.15.3.1.3](#).

Turning now to solid particle erosion, it is tempting to assume that solid particle erosion rates would also be inversely dependent on the surface hardness,  $H$ , as predicted by simple plastic deformation erosion models, [eqn \[3\]](#), where  $\alpha$  is the erodent impact angle. A more complex model, also given by Hutchings,<sup>8</sup> includes the critical strain concept, [eqn \[4\]](#) and this predicts the erosion should be dependent on  $H^{3/2}$ . However, these relationships rarely hold in practice for engineering materials.

Erosion models

$$E_r = \frac{K \rho_T U_p^n}{H} f(\alpha) \quad [3]$$

$$E_r = \frac{K_1 \rho_T \rho_P^{1/2} U_p^3}{\epsilon_c^2 H^{3/2}} \quad [4]$$

where:  $K$  is a constant,  $\rho_T$  is the density of the target,  $\rho_P$  is the density of the particle,  $U_p$  is the particle velocity, and  $\epsilon_c$  is the critical plastic strain.

Corrosion resistant alloys (CRAs) are widely used to resist flow corrosion. For example, chromium is added to improve the resistance to flow corrosion of carbon steel (CS), see Poulson.<sup>9</sup> [Figure 3](#) shows the trend for such a passive system (where passive means that the surface has a propensity to form a protective surface film or layer with high impedance and thus suppresses charge transfer at the metal–

liquid interface) as a function of flow velocity and its vulnerability to mechanical processes, which accelerate corrosion loss rates. In general, corrosion-resistant alloys do not resist erosion well and the interactions that exist between corrosion and erosion are not well understood. These interactions are sometimes referred to as synergistic or antagonistic. These terms refer to the possibility that simple summing of the mechanically induced material loss without a corrosive contribution and the electrochemical (corrosion) material loss without mechanical stimulus does not give an accurate material loss for tribocorrosion conditions. Some surface–environment conditions suffer accelerated material loss where the actual loss rates are higher than the simple summation of the pure mechanical and electrochemical levels. This case is termed ‘synergistic,’ while combinations of surface/environment that result in reduced material loss and are below the levels of the simple summation are termed ‘antagonistic’ (negative synergy). This presents a dilemma for those seeking erosion–corrosion-resistant surface selections. Also, cost reduction considerations favor replacing expensive solid alloy components with coatings on CS substrates, and hence, considerable effort is now being made to research coating performance under erosion–corrosion.

#### 2.15.2.1.2 Environment factors

Corrosion is a reaction process on metallic surfaces that occurs as a result of interaction with the environment. The rates and modes of corrosion attack are

**Figure 3** Arbitrary flow corrosion rates versus flow velocity.

related to the environmental conditions such as pH, dissolved oxygen, salinity, temperature, flow structure, and whether biofouling occurs. The latter point is often ignored but can have dramatic effects.

The influence of environmental factors on erosion-corrosion is likely to be very system dependent. However, the sensitivity of wall wastage rates to such environmental parameters can be found in the literature. Kim *et al.*<sup>10</sup> report how these parameters effect the galvanic corrosion of CS in alkaline-chloride solutions. They studied the aqueous corrosion characteristics of a CS coupled to type-304 (UNS S30400) stainless steel in deaerated solutions as a function of velocity, pH, and temperature. They found that the galvanic corrosion between CS and type-304 stainless steel was effected by the presence of an oxide layer formed on the CS. The galvanic current density increased with increasing flow velocity (between 0 and  $0.6 \text{ m s}^{-1}$ ) and temperature (between 25 and  $75^\circ\text{C}$ ), but decreased with increasing pH from 8 to 10. Flow velocity effects were only significant at 50 and  $75^\circ\text{C}$ . This effect can be explained by the increased solubility of magnetite (corrosion oxidation product) at the higher temperatures. The importance of passive films and their stability will be addressed in more detail later in this chapter.

Proteinaceous material present in natural joint lubricants can play an important influence within biomedical implants, particularly on metallic joint surfaces. Research has shown that proteins have different affinities for different metals, probably as a result of various ligands in their molecular structure that have different bonding energies and therefore different affinities for specific cations.<sup>11</sup> The effect of albumin (a protein found in serum) on the corrosion rate of biometallic materials is varied with Al and Ti being unaffected, Cr and Ni showing a slight increase, while Co and Cu dissolve at a much greater rate.<sup>12</sup> Williams *et al.*<sup>13</sup> found that the corrosion rate of stainless steel and commercially pure titanium increased when exposed to proteins in a static environment, while under fretting contact conditions, proteins were found to decrease the corrosion rate of the stainless steel but had little appreciable effect on titanium alloys. In a recent study on the effect of synovial fluid (SF) on corrosion properties of CoCrMo alloys,<sup>14</sup> proteins were found to be absorbed on the surface. It was hypothesized that protein (normally negatively charged) adsorbs to generate a film that reduces the corrosion rate by acting as a negatively charged barrier preventing corrosive anions (e.g.,  $\text{Cl}^-$ ) approaching the CoCrMo interface. Contu *et al.*,<sup>15</sup>

on the other hand, attributed the reduction in corrosion rate of CoCrMo in bovine serum (BS) to the anodic dissolution process being under diffusion control resulting in positive shifts in surface potentials compared with inorganic solutions at the same pH. Goldberg *et al.*<sup>16</sup> carried out a series of scratch tests on CoCrMo (ASTM F75) samples and found a decrease in peak currents (decrease in corrosion rate). The authors attributed this to the barrier effects of the adsorbed protein preventing water from reaching the sample surface, or lubrication resulting in less material removed from the surface during scratching.

A guide to system performance for solutions with different pH can be found by reference to the relevant potential–pH (Pourbaix) diagram. This approach has been illustrated by Stack<sup>17</sup> in a regime mapping approach to erosion-corrosion and by Celis<sup>18</sup> for sliding wear-corrosion contacts.

The influence of the bulk oxygen concentration,  $C_b\text{O}_2$ , in aqueous environments on the corrosion rate depends on the controlling corrosion mechanisms, which will be discussed in greater detail later in the chapter. The dramatic influence of oxygen levels on fretting wear-corrosion rates of a type-304L stainless steel sleeve fretting against a 304L tube in simulated nuclear plant conditions using boric acid with Lithine (an inhibitor) at a pH of 8.7 is illustrated in Figure 4 from Deforge *et al.*<sup>19</sup> It is also interesting to see that most tribocorrosion occurs on the sleeve for systems

**Figure 4** Fretting wear loss of stainless steel type-304L tubes in contact with a stainless steel type-304L sleeve after 1 week in boric acid + lithine, pH = 8.7 at room temperature. The OCPs for the deaerated (overpressure of hydrogen) and aerated conditions were  $-0.630$  and  $-0.030 \text{ V}$  versus SHE, respectively. Reproduced from Deforge, D.; Wenger, F.; Ponthiaux, P.; Lina, A.; Ambard, A. Tribocorrosion of AISI 304L stainless steel sliding against AISI 304L stainless steel in nuclear environment, 207th Electrochemical Society Meeting, Quebec City, Canada May 2005, session E1 on Chemical, Electrochemical, and Mechanical Effects on CMP, Tribocorrosion, and Biotribocorrosion, abstract #313.

exposed to flow, and under mass transport control, the corrosion rate can be found to be directly proportional to  $C_bO_2$ , or  $C_bO_2^n$ , where  $n$  is flow and system dependent.

Temperature of the surfaces is an important variable which can influence wear-corrosion rates and hence the temperature of the environment, be it air or lubricant, must be taken into account. In addition, many contacts between surfaces in relative motion result in an increased heating of the contact zones due to friction. In aqueous solutions, temperature not only influences the pH, solubility of gases (i.e., oxygen and carbon dioxide), and ionic species as well as diffusion rates of reactant species but can also affect the kinetics of oxidation reaction at the oxide-metal interface and the dissolution of oxides at the oxide-water interface. Added complications can occur when elevated temperatures increase hydrogen diffusion rates, and if this effect is coupled with a surface susceptibility to hydrogen embrittlement, then increased wall loss can result.

In nuclear power plant, the effect of water chemistry has been shown to strongly influence the wear rates of 304L stainless steel in pressurized high temperature water. The high temperature of the water promotes thicker oxide layers that are harder due to the formation of micron-sized magnetite crystallites. If these layers are detached and stay within the contact, they can create very abrasive (rolling abrasion where entrained oxide particles roll and indent the contact surfaces) wear conditions. For low-pH waters between 5 and 7, Kaczorowski<sup>20</sup> reports dramatic increases in material loss by the promotion of such three-body mechanisms and by decreasing the electrochemical potential in the electronegative direction.

Another major environmental factor with significant influence on erosion-corrosion rates is that of flow (see **Chapter 2.13, Flow Assisted Corrosion**), but care needs to be taken to use appropriate flow characterization parameters. For example, a single value of flow velocity referred to as the critical velocity is often quoted to represent a transition from flow corrosion to enhanced mechanical-corrosion interactive erosion-corrosion processes. It is also used to indicate the resistance of the passive and protective films to mechanical breakdown.<sup>21</sup> However, it should be remembered that a single value of free stream velocity can result in widely different flow field structures that are dependent on the Reynolds number of the flow geometry and type and thickness of boundary layer induced at the liquid-solid interface. These factors will directly affect the velocity profiles and

transverse momentum transfer close to the solid-liquid interface, which will be shown later to influence the thickness of the boundary and subviscous layers and thereby dictate wall shear stress levels and mass transport efficiencies. Therefore, critical velocity values are very geometry or test rig specific and can not be readily applied to predict component service life in generic flow systems.

Poulson<sup>9</sup> has investigated the effects of flow on corrosion of CS and the effects of depassivation of the surface (see **Figure 5**). The corrosion of CS in neutral solutions is governed by the reduction of dissolved oxygen as shown in eqn [5].

This cathodic electrochemical reaction drives the anodic dissolution of iron, in eqn [6].

Poulson reported that the flow corrosion rate was closely related to the mass-transport coefficient. However, under detached/separated flow conditions (such as flows through sudden expansion pipe work), the rate can be independent of flow.

Al-Hosani *et al.*<sup>22</sup> have studied the galvanic corrosion induced by the coupling of copper-based alloys to Mo-stainless steels in static Arabian Gulf seawater under a variety of conditions including temperatures, cathode-anode area ratios and stirring. For static conditions, the corrosion rates were found to be proportional to the cathode-anode area ratio. This can be attributed to the fact that the cathodic reaction (the reduction of oxygen) controls the overall corrosion process, and this is diffusion controlled. However, the galvanic corrosion rate of the couples increased nonlinearly with a rise in temperature to reach a maximum at 50 °C, decreasing sharply at higher temperatures due to the decreased solubility of  $O_2$  in solution at this temperature. The effect of stirring the electrolyte shifted the open circuit

**Figure 5** Corrosion of carbon steel (CS) activated by wear that depassivates surface in the wear track.

potential (OCP) of the stainless steel to a more electro-negative value. Thus, the corrosion rates in the stirred solutions were found to be 1.33–3.0 times above those measured in stagnant solutions.

Erosion-corrosion conditions can themselves develop local microgalvanic cells between eroded and uneroded surface areas. Such microgalvanic cells have been reported between erosion-affected regions (depassivated) of a surface and noneroded regions (passive). For example, enhanced material loss rates due to such galvanic cells are reported by Hodgkiess.<sup>23</sup>

The environment can change the wear mechanism and thereby the wear rate and life of surfaces. This is illustrated by the tribological properties of plasma-sprayed Cr<sub>2</sub>O<sub>3</sub> coatings, studied by Wei,<sup>24</sup> at room temperature, using distilled water, water-ethanol, *n*-monohydric alcohols, and polyhydric alcohols as lubricants. Testing indicated that both friction and wear were much higher (approximately twice) in water than in the *n*-monohydric alcohols. Analysis of the morphology and composition of the worn surfaces indicated that the wear of Cr<sub>2</sub>O<sub>3</sub> coating was controlled by the combination of microfracture and tribochemical wear in water and was only controlled by microfracture in ethanol.

### 2.15.2.1.3 Friction

Friction is the resistance force encountered when surfaces in contact move relative to each other. A popular way to express this force in terms of a loaded sliding contact is by using the dynamic coefficient of friction,  $\mu$ , defined as the frictional force,  $F_f$ , divided by the normal load,  $W$ , on the contact when the contact is sliding.

$$\mu = \frac{F_f}{W} \quad [7]$$

For lubricated contacts in relative motion separated by a film of lubricant, the dynamic coefficient of friction,  $\mu$ , is typically very low ( $<0.1$ ) and can be as low as 0.1, even when the lubricant film is only a few nanometers thick. These values compare with values of  $\sim 1.0$  for unlubricated dry sliding. Friction between contacting surfaces in relative motion results primarily from forces acting perpendicular to the applied load. As the fluid film thins, the interaction of surface asperities can cause increases in friction. Water, however, is regarded as a poor lubricant, as it does not form a fluid film readily or support loads due to a minimal pressure–viscosity interaction. However,

water-lubricated contacts reduce the contact temperature compared with dry contacts and aqueous lubricants are being considered as an environmentally acceptable alternative to hydrocarbon-based oils. It should be noted that the friction force required to be overcome to induce relative motion in a contact can be used in eqn [7] and  $\mu$  is then termed the static coefficient of friction and is typically higher than the dynamic values.

Bowden and Tabor<sup>25</sup> proposed a model, which in its simplest form assumes that frictional forces arise from adhesive forces and deformation forces induced by the abrasive ploughing nature of the harder asperities interacting with the softer ones of the counter surface. The adhesive force is linked to the asperity–asperity contact, which makes up the real area of contact between surfaces and the junctions between them. The shear strength of these junctions influences the level of friction. Adhesive effects are thought to be due to the summation of interfacial intermolecular interactions that operate at the asperity contacts. There are also likely to be some chemical processes activated within the contact, such as oxidation, which can form coherent films and their composition can influence friction levels. The presence of oxide layers and adsorbed films on metal surfaces generally weakens the shear strength of the asperity junctions and thus lower adhesive forces resist motion resulting in lower friction. For example, a multilayered film can be formed on ferrous surfaces under dry sliding, typically with FeO close to the surface, which is covered by a layer of Fe<sub>3</sub>O<sub>4</sub>, which in turn is covered by Fe<sub>2</sub>O<sub>3</sub>. The Fe<sub>2</sub>O<sub>3</sub> layer is associated with high friction ( $\mu = 1.1$ ), but if this layer is penetrated exposing the sublayers, then lower friction ( $\mu = 0.5$ ) can result.<sup>26</sup> However, for soft ductile metals, and where the oxide layers or adsorbed films are partially removed, appreciable adhesion between nascent (freshly formed or exposed material) surfaces can result. Adhesion can also be enhanced if similar surfaces are in contact, that is, stainless steel pairs.

### 2.15.2.2 Corrosion and Associated Electrochemical Reactions

This section reviews the relevant corrosion reactions related to tribocorrosion and the important role of the surface films formed under tribocorrosion conditions called tribofilms.

### 2.15.2.2.1 Tribofilms

Published research has tried to deal with the synergistic and antagonistic effects between erosion and corrosion processes, which result in accelerated material loss (synergism) or in some cases actually decelerate material loss (antagonism, sometimes called negative synergism).<sup>27–31</sup> A wide range of corrosion-resistant materials relies on a relatively thin surface film to provide a barrier (of high impedance) to charge transfer (and thus corrosion) between the relatively active bulk material and the corrosive environment. The thickness of such films is dependent on time, temperature, interfacial potential, pH, and the environment (i.e., species concentration and type). The films range from being tens of Angstroms to hundreds of Angstroms thick and are formed in relatively short times, typically <1 s. These films render the surface passive, but for fluid machinery handling flows where solid particles have been entrained or cavitation is induced, the passive film can be removed by mechanical wear or bubble collapse/microjet/shockwave impingement processes. Where the film is mechanically removed, charge transfer can occur at the interface without retardation from the barrier film.<sup>32</sup> The stability of these surface films will depend on their adherence to the parent bulk material and their cohesive strength when subjected to contact stresses. The solubility of the surface films within the changing environment of tribocontacts will also influence the stability and could instigate compositional changes in the surface film. Clearly, density and hardness of the surface films will influence the micro-contact mechanics of tribological processes of wear and friction.

Similar mechano–electrochemical processes occur in sliding contacts where tribochemical wear occurs by detrimental chemical reactions within the contact, induced by the local environment, and in combination with the mechanical contact mechanisms and induced stress fields. Contact between the sliding surfaces can accelerate chemical and electrochemical reactions and material removal. Sliding contact results in increased surface temperatures and can induce surface cracks and the generation of nascent surfaces, which are highly reactive with their environment. However, the chemical formation of surface films can be advantageous, as they can have low friction properties and also promote material transfer to change the contact from base–base material to chemical film–chemical film and thus change the contact conditions.

The interaction between the tribofilms formed on interacting surfaces often results in nanometer-thick

mechanically mixed layers that are formed in the shear zone between the contacting surfaces. These layers are often a mixture of components from both surfaces generated by material transfer but also contain corrosion products, wear debris, and remnants of any passive film, if the surfaces are passive metallic systems. This layer is often referred to as the tribofilm and its composition and thickness will control the level of tribocorrosion at the contact when sliding wear occurs in a corrosive environment. The environment clearly has an influence on the composition of the film. For example, the environment will determine whether oxides or sulfides can form or whether calcium carbonate (chalk)-based films can form.

Mischler *et al.*<sup>33</sup> show the importance of the passive film in controlling wear rates and friction when testing CS in borate solution (pH 8.4). They reported two concurrent mechanisms: (1) oxidative wear involving the detachment of passive film followed by repassivation; and (2) surface disruption by abrasion, subsurface deformation, and cracking. Interestingly, when held at cathodic potentials, there was no film present and asperity interaction resulted in debris being smeared over the wear track, subsequently decreasing the wear rate.

A mechanistic view given by Staehle<sup>34</sup> looks at the initial interaction of dislocations in the metal substrate with surface films in terms of single and cross-slip and conditions for perforating these films. This approach suggests that the significant properties of initial films in terms of interaction with dislocations are plasticity, strength, stacking fault energy, and epitaxy. Other factors to consider are the duration in which the surface is totally or partially film-free, the kinetics of film-free and repassivation regions, and the dependence of these film-free and repassivation regions on pH, potential, environment, alloy composition, temperature, mass-transport, and contact-induced stress. Staehle shows that film-free areas only represent 10% of the surface area affected, as repassivation occurs very quickly under high-speed/strain elongation tests. It was also found that the reaction rates on the mechanically affected surface areas were one to two orders of magnitude higher than nonaffected areas. This emphasizes the importance of film integrity in minimizing corrosion rates. Staehle concludes that increasing the chromium content or the presence of a Molybdate inhibitor increased the rate of repassivation of steels. However, increasing the concentration of sulphates and the presence chlorides reduced the rate of repassivation.

### 2.15.2.2.2 Depassivation and repassivation kinetics

#### Depassivation

Depassivation in tribocontacts involves the rapid removal of the surface layers and sometimes the underlying bulk material by mechanical action such as surface abrasion, adhesion, plastic deformation, cutting, thermal cycling, fatigue and particle erosion, cavitation bubble, or liquid droplet impact mechanisms. For example, Figure 6 illustrates the level of damage to passive films as a function of solid particle impingement angle. Mechanical removal and/or rupture of the passive layer enables charge transfer to proceed at varying rates and parent metal dissolution is likely. 'Recovery' or repassivation aspects of the passive film are therefore important. Figure 7 shows the current response over time for individual solid particle impacts on the naturally passivating system of stainless steel in a NaCl solution. Some impacts will only result in partial passive layer removal or cracking, which will influence repassivation kinetics and possibly the composition of the regrown layer.

Mechanical deformation that disrupts and perforates passive films takes place by dislocation movement. Dislocation interaction with the passive film

can lead to rupture and/or perforation that results in a transient exposure of highly reactive parent material. This process is sometimes referred to as 'slip dissolution.' The degree of disruption to the passive film depends on whether the slip is concentrated on a single plane or is diffuse on multiple planes as with cross-slip. An illustration of a passive film disruption by slip in a single plane is shown in Figure 8. As Figure 8 (b) shows, if the displacement is great enough, corrosion occurs under the passive film, which will further compromise the integrity of the film if subjected to further deformation in a tribocontact.

#### Repassivation

Surface coverage models for passive film growth/recovery typically relate to steady state film formation and are not applicable to transient events of  $<1$  s duration, which are often found in tribocorrosion. However, these models are useful and they consider the number of moles of oxide formed  $N_u$  as a ratio of the total number of surface sites available,  $N_{o,u}$ , in units of  $\text{mol cm}^{-2}$  (from Jemmely *et al.*<sup>35</sup>):

$$\theta = \frac{N_u}{N_{o,u}} \quad [8]$$

The rate of lateral surface coverage during early stages of repassivation of nascent surfaces, assuming complete oxidation of the parent metal to oxide, can be given by

$$\frac{d\theta}{dt} = i \left( \frac{M_{ox}}{L_{ox} \rho_{ox} z F} \right) \quad [9]$$

where  $i$  is the anodic current density,  $z$  is the charge number,  $L_{ox}$  is the oxide film thickness,  $\rho_{ox}$  is the oxide density, and  $M_{ox}$  is the molar mass of the oxide.

**Figure 6** Schematic showing that the level of passive layer damage is dependent on particle impact angle.

**Figure 7** Current transients in erosion–corrosion due to depassivation/repassivation. Reproduced from Sasaki, K.; Burstein, G. T. *Philos. Mag. Lett.* **2000**, *80*(7), 489–493.

**Figure 8** (a) Dislocation on a single slip plane with the surface covered by a thin passive film (b) dislocation is more extensive and film is perforated and corrosion occurs under passive film. Reproduced from Staehle, R. W. *Corros. Sci.* **2007**, 49, 7–19.

If Tafel kinetics applies then the anodic current density  $i$  can be given by

$$i = k_a(1 - \theta)\exp\left(\frac{E_{\text{applied}}}{b_a}\right) \quad [10]$$

where  $k_a$  is the rate constant and  $b_a$  is the Tafel slope ( $=dE/d\ln i$ ). This assumes that oxidation occurs exclusively on bare parent metal.

Film growth models may then be used to explain the thickening of oxide layers. These models assume growth occurs by high field conduction which is thought to apply over the longer term and are therefore not applicable in the early stages of repassivation of nascent surface sites.

$$i = k_B \exp\left(\frac{B\Delta\varphi}{L_{\text{ox}}}\right) \quad [11]$$

where  $k_B$  is the rate constant and the migration kinetic constant for a single ionic species  $B = \alpha_1 z F a_j / RT_s$ . Here  $\alpha_1$  is a symmetry constant,  $z$  is the charge on the migrating ionic species, and  $a_j$  is the jump distance. The term  $\Delta\varphi$  is the potential difference across the oxide layer and taken to be the difference between the electrode potential and the minimum potential for the initiation of film growth. The other term in the equation is the oxide layer thickness,  $L_{\text{ox}}$ .

This can be linked to the current–time transients by setting:

$$L_{\text{ox}} = \frac{M_{\text{ox}} q}{z F \rho_{\text{ox}}} \quad [12]$$

Where  $q$  is the charge passed or  $\int i dt$ .

The use of such models to predict wall loss rates under depassivation–repassivation conditions depends

on the assumptions mentioned earlier and knowing the oxidation process and the associated charge number as well as the area of depassivation due to the wear processes. Some of the possible environmental factors that effect depassivation and repassivation are summarized for erosion–corrosion in [Table 2](#).

Thus, if the contact conditions allow, the rupture of the passive film can be repaired as shown schematically in [Figures 9–11](#). This is an ideal case where accelerated dissolution of the substrate is minimal. Obviously, more severe abrasion would result in accelerated corrosion by inhibiting effective repassivation.

#### 2.15.2.2.3 Critical velocity concept

The velocity profile established between flowing electrolyte and a solid surface, see [Figure 12](#), generates a maximum shear stress at the wall–liquid interface.

The wall shear stresses can be calculated from [eqn \[13\]](#).

$$\tau_w = (\mu + \eta) \frac{dU}{dy} \quad [13]$$

where  $\mu$  is the dynamic viscosity of fluid,  $\eta$  is the turbulent eddy viscosity, and  $dU/dy$  is the velocity gradient at the wall. For laminar flows, the turbulent eddy viscosity can be set to zero.

These are stresses that could be applied to loosely adherent surface deposits/layers or passive films and change mass-transport conditions thereby influencing flow corrosion and erosion–corrosion. However, it is now thought that passive film removal and its associated critical velocity is related to mass-transport-induced

**Table 2** Possible influences on the depassivation and repassivation kinetics, adapted from Wood<sup>27</sup>

<i>Environmental Factor</i>	<i>Depassivation processes that cause passive film removal or disruption</i>	<i>Repassivation processes that encourage regrowth (repair) of the passive film</i>
Solid particle impact	Plastic deformation or cutting	Enhanced repassivation on plastically extruded regions
Surface/liquid interface	High velocities/wall shear stresses	Film growth kinetics(monolayer coverage plus lateral film growth)
Occluded geometries/pits	Local environment changes such as low pH	Metastable pits
Contact stress/shear stress/thermal pulse by frictional heat	Destabilises and delaminates passive film	Thermal pulse enhances film regrowth
Temperature	Local temperature	Local temperature
Turbulence bulk flow structure	Turbulent flow features shear the film from surface	Rougher/larger surface area

mechanisms (surface dissolution and polarization) and not wall shear stress,  $\tau_w$  (see eqn [13]), as previously assumed.

For single-phase turbulent flows in pipes, a ‘break-away’ or ‘critical velocity’ above which damage occurs to pipe surfaces has been reported based on

**Figure 12** Near-wall velocity profile.

the principles of the critical wall shear stress required to strip the passive film off the pipe surface. **Table 3** lists typical values for various copper alloys in pipe geometries handling seawater.

#### 2.15.2.2.4 Flow corrosion

Flow corrosion is defined as the corrosion resulting from the effect of flow of a fluid that does not contain solid particles in sufficient concentration and/or size to impinge on the metal surface.<sup>37</sup> The reactants are transported to a metal surface by diffusion or convection, while the products must be removed by the same mass transport mechanisms or accumulate as scales.<sup>38</sup>

Corrosion models have been developed over the years that have attempted to establish the relationship between fluid dynamics, mass transport, and ultimately the chemical and electrochemical reactions that occur on the surface of a metal. These

models have recently been discussed in a series of papers by Nesic *et al.*<sup>39</sup> The models describe the formation of protective scales and assess quantitatively the conditions (chemical and hydrodynamic) under which scales form, and only consider the dissolution of such scales. These models tend to neglect the lateral momentum transfer associated with turbulence, which are now considered important in understanding flow corrosion.

Mass transfer of reactants to and from the electrode surfaces plays an important role during flow corrosion where the dissolved oxygen or the dissolved metal ions have to diffuse from the solution to the metal or from the metal to the solution, respectively.<sup>40</sup> Mass-transport has been studied by several authors in different hydrodynamic systems that use convection to enhance the rate of mass transfer to the electrode. Such devices include free and submerged

jet impingement geometries, rotating disc electrodes (RDE), and rotating cylinder electrodes (RCE). However, recently, the microwall jet electrode (WJE) has been deployed to investigate the quantitative electrochemistry during process flows.

The standard model used to describe flow corrosion current densities for mixed controlled reactions (where activation and diffusion processes are present) is the modified Koutecky–Levich model<sup>41</sup> given in eqn [14], where  $k_m$  (the mass transport coefficient) can be derived from eqns [29]–[31], will need correcting. Equation [14] is the summation of activation current density,  $i_a$ , which is controlled by the charge transfer kinetics and the diffusion controlled current density,  $i_d$ , which is related to the mass transport of species to and from the reacting surface.

$$\frac{1}{i} = \frac{1}{i_a} + \frac{1}{i_d} = \frac{1}{zFk_1} + \frac{k_{-1}}{k_1 zFk_m} \quad [14]$$

where  $i$  is the corrosion current density,  $n$  is the number of electrons,  $F$  is the Faraday's constant,  $k_1$  is the forward reaction rate, and  $k_{-1}$  is the backward reaction rate.

The values of  $k_m$  are normally obtained from non-dimensional correlations between the Sherwood number  $Sb = (k_m L/D)$ , the Schmidt number  $Sc = (\nu/D)$ , and the Reynolds number  $Re = (UL/\nu)$ .

$$Sb = aRe^x Sc^y \quad [15]$$

Giving

$$k_m = aD^{1-y} L^{x-1} \nu^{y-x} U^x \quad [16]$$

Taking typical values for the exponents as  $x=0.6$  and  $y=0.33$  for turbulent pipe flows where  $2000 < Re < 5000$ <sup>9</sup> gives

$$k_m = aU^{0.6} \left( \frac{D^{0.66}}{\nu^{0.27} L^{0.4}} \right) \quad [17]$$

where  $D$  is the diffusion coefficient,  $U$  is the flow velocity,  $\nu$  is the kinematic viscosity,  $L$  is the characteristic length, and  $a$  is the scaling constant.

Flow corrosion rates induced by solids-free flows, as suggested by eqn [14], have been shown to depend on  $k_m^n$  where  $n$  varies depending on the surface–environment combinations and the controlling corrosion mechanism. For example, corrosion rates for copper alloys in seawater under partial activation or mixed control are shown to have  $n < 1$ . Steels in sulfuric acid and under simple mass transfer control have  $n = 1$ ; while for steels in water where flow modifies the corrosion potential and also influences the solubility of the oxide,  $n$  lies between 1 and 3, see Poulson.<sup>9</sup> The rates of

mass-transport processes also increase with increasing surface roughness. For pipes, different relationships apply depending on the surface finish. When surface roughness is developed on a pipe wall, the rate of mass transfer is proportional to the flow turbulence or the velocity distribution in the laminar sublayer.<sup>36</sup> For a fully eroded pipe with so-called scalloped surfaces where erosion scars resemble inverted scallop shells

$$Sb = 0.005 Re Sc^{0.33} \quad [18]$$

For a previously roughened pipe

$$Sb = 0.007 Re^{0.96} Sc^{0.33} \quad [19]$$

The upper bound value is reached for extremely rough surfaces and given by

$$Sb = 0.01 Re Sc^{0.33} \quad [20]$$

However, a power-law relationship between erosion-corrosion rate and  $k_m$  is not always seen as in the case of steel where surface films are removed above a critical  $k_m$  resulting in a sudden increase in erosion-corrosion rate.

It has also been proposed that corrosion films/coatings can also be damaged and/or completely removed by mechanical forces resulting from the impact of either small fluid packages contained in eddies and/or bubbles created by highly turbulent flows.<sup>42</sup> Attempts to quantify the effective hydrodynamic forces in terms of wall shear stresses have been confronted with the problem that the measured wall shear stresses in flow corrosion susceptible systems are orders of magnitude too small,<sup>43,44</sup> even under highly disturbed flow conditions, to overcome the fracture mechanics of the surface scales. It has been calculated that the destruction of such layers would require shear forces of the order of 1 MPa, while measurable wall shear stresses, even in highly turbulent flow, are only of the order of 1 Pa,<sup>45</sup> and thus are too small to be the right parameter to quantify hydrodynamic forces responsible for the initiation of flow corrosion. Nevertheless, critical flow intensities are undoubtedly identified in terms of critical wall shear stresses above which corrosion products are hydrodynamically damaged. This leads to the significance of lateral momentum transfer by the near-wall turbulence structures in the hydrodynamic boundary layer that disturb scales and/or protective films.<sup>42–45</sup>

The near-wall region can be divided into three distinct regions: (1) the viscous sublayer, (2) the buffer layer, and (3) the fully turbulent region. Turbulent features are often reported with reference to the dimensionless scale  $y^+ = v^* y/\nu$ , where  $v^*$  is the

friction velocity ( $=\tau_w/\rho$  or wall shear stress over fluid density),  $y$  is the vertical height above a horizontal surface, and  $\nu$  is the kinematic viscosity of the fluid. The viscous sublayer extends from the wall out to  $y^+ = 5-8$ . In this region, the mean velocity profile is linear and it is assumed that this region is devoid of turbulence. However, flow visualization has revealed slow-moving oscillations known as near-wall or sub-layer streaks.<sup>46,47</sup> These streaks are  $\sim 100y^+$  units across and  $1000y^+$  units long and are believed to occur as a result of elongated regions of alternating low- and high-speed fluid produced by streamwise vortices close to the wall. The near-wall streaks slowly lift up into the buffer region, where they undergo a distinct oscillation and finally break up violently  $\sim y^+ = 40$  (see **Figure 13**).<sup>48,49</sup> The majority of the turbulence production occurs in the buffer region from  $y^+ = 8$  to 30 to 50 during violent outward ejections of low-speed fluid and for continuity considerations, the ejections are followed by a sweeping inrush of high-speed fluid at a shallow angle toward the wall. An ejection transports low-momentum fluid from the wall region into the main flow. Conversely, sweep events transport high-momentum fluid from the main flow toward the wall (**Figure 13**) at velocities close to  $0.9U$ , where  $U$  is the free stream velocity. The result of these flows is fluctuating wall shear stresses, see **eqn [13]**, and pressures which will influence erosion-corrosion rates and mechanisms locally.

### 2.15.2.3 Wear Fundamentals

#### 2.15.2.3.1 Solid particle erosion

To understand erosion-corrosion, it is desirable to first understand the erosion mechanisms. Solid particle erosion in liquid systems is a process by which

discrete small solid particles that are suspended in the flow, with inertia, strike the surface of a material causing damage or material loss to its surface. Erosion can be a problem for components such as gas and hydraulic turbine blades, propulsors, pipelines, valves and fluidized bed combustion systems. An example of the surface features erosion can develop in flow through a valve is shown in **Figure 14**. Erosion does have its beneficial applications, notably for cleaning and preparation of surfaces for subsequent coating/painting, descaling/dewaxing of production risers in the oil and gas industries, oil sand transportation, hydrotransport systems and quarrying rocks using abrasive cutting jets, or subsea steel oil structures using submerged abrasive water jets.

The flow conditions along with the properties of the target material or any film, if present, as well as the fluid and erodent properties will influence the contact mechanics of the erodent to component surface interactions. The main important target material properties are hardness, fracture toughness, coefficient of restitution elasticity, and the degree of surface roughness. The general expression for erosion rate,  $E$ , has been established empirically and can take the form

$$E = M_p K f(\alpha) U_p^n \quad [21]$$

where  $M_p$  is the mass of particles impacting on the surface,  $U_p$  is the particle velocity on impact,  $\alpha$  is the particle impact angle,  $K$  and  $n$  (typically between 2 and 3)<sup>50</sup> are constants assumed to be dependent on the characteristics of the erodent/target materials involved, and  $f(\alpha)$  is a functional relationship for the dependence of the erosion rate on the impact angle.<sup>51</sup>

**Figure 13** Schematic showing the near-wall turbulence structures within the viscous sublayer, buffer layer, and fully turbulent region.

**Figure 14** Sand erosion patterns of a Stellite tapered flow passage located downstream of a choke valve that induced swirl flow. Large bore is 75 mm in diameter.

This can be rewritten for the unit volume loss per impact,  $V_u$ , as

$$V_u = E_k^m f(\alpha) C_v G \quad [22]$$

where  $V_u$  is the volume loss per impact in units of  $\text{m}^3$  per impact,  $E_k$  is the particle kinetic energy (KE),  $m$  is the energy exponent with  $m = 0.5n$  assuming  $E \propto d^3$  where  $d$  is the particle diameter,  $C_v$  is the volume fraction,  $G$  is a constant, and  $f(\alpha)$  is as before. From eqn [21] or [22], it can be seen that the erosion rate will be strongly dependent on the KE of the impacting particles, the number of impacting particles, and the impact angle. All three of these factors vary for most industrial components exposed to solid particle-laden flows, and therefore, to sustain long service life, the internal surfaces must perform over a wide range of solid impact conditions. The sand-to-wall impact conditions are likely to depend on the flow regime present, the orientation and/or geometry of the component, the ability of the flow to keep the particles in suspension<sup>52</sup> and the relative size of erodents with respect to boundary layer thickness (small particles can form protective clouds within subviscous layers). For suspended solids traveling in a horizontal liquid flow, both the solid particle impact velocities ( $< 3.0 \text{ m s}^{-1}$ ) and angles are relatively low for most practical purposes.<sup>53</sup> Typical impact erosion craters are shown in Figure 15.<sup>54</sup>

Plots of  $V_u$  against KE of impact,  $E_k$  can be used to map the erosion performance of surfaces. These maps enable comparisons to be made between materials

**Figure 15** SEM micrographs of 0.2% CS (a)  $7 \text{ m s}^{-1}$  and (b)  $12 \text{ m s}^{-1}$ , 1 wt.% silica ( $296 \mu\text{m}$ ) sand in 0.1 M NaOH at  $40^\circ\text{C}$ , test time = 30 min. The eroded region observed was located approximately normal to the flow and in the center of the sample. Reproduced from Harvey, T. J.; Wharton, J. A.; Wood, R. J. K. *Tribology – Mater. Surf. Interfaces* 2007, 1(1), 33–47.
